$D \preceq E$ requires D, E to be systems over a *common* token type a . The abstract functor T need not preserve token types: $T.\text{obj} \langle a, D \rangle$ and $T.\text{obj} \langle a, E \rangle$ may have different carriers. So " $T(D) \preceq T(E)$ " only makes sense once we *assert* that T preserves the token type along $\preceq$, i.e. once the carriers of the two images agree. **Monotone on domains** therefore packages, for each $h : D \preceq E$:

- * carrier_eq : the two image carriers coincide;
- * sub : the transported subdomain relation $T(D) \preceq T(E)$;
- * $\text{inj_heq}/\text{proj_heq}$: Scott's "the projection pair i, j is mapped to $T(i), T(j)$ ", i.e. the canonical 6.12 pair of $T(D) \preceq T(E)$ is exactly $(T.\text{map } i, T.\text{map } j)$ (stated up to the carrier transport, hence HEq).

Continuous on domains then adds Scott's approximability of $\text{fun } D. T(D)$, rendered in the concrete neighbourhood framework as *preservation of directed unions of subsystems*: for any directed family $\preceq$ of subsystems of E whose union is the subsystem U , the (target-side) neighbourhood family of $T(U)$ is the union of those of the $T(D)$. This is exactly the continuity Scott invokes in the proof of 6.14 ($T(\varinjlim T(\Gamma)) = \varinjlim T(T^{n+1}(\Gamma))$).

The identity functor is monotone and continuous on domains ($\text{monotoneOnDomains_id}$, $\text{continuousOnDomains_id}$), witnessing non-vacuity. Everything is **choice-free** ($\text{\#print axioms subseq \{proptext, Quot.sound\}}$).

# Lecture VI -- Theorem 6.14 (Scott 1981, PRG-19): existence of initial `T`-algebras

> **THEOREM 6.14.** If the functor `T` is continuous on maps and monotone and continuous on
    domains,
> and if there is a set `Gamma` such that `{Gamma} ? T({Gamma})`, then there exists an initial
    `T`-algebra.

Scott's proof iterates the functor from the generating system `{Gamma}`. The assumption
`{Gamma} ? T({Gamma})` means `T({Gamma})` is a system over the same token set `Gamma`;
    iterating, every
`T?({Gamma})` is over `Gamma` and `T?({Gamma}) ? T?^+1({Gamma})`. The colimit
`? = ?_n T?({Gamma})`

is then a system over `Gamma` with `T?({Gamma}) ? ?`, whence `? ? T(?)`, and *continuity on
    domains*
gives `T(?) = ?` -- the isomorphism `? ~ T(?)` is the **identity**. So `?` is a `T`-algebra,
    and:

* **existence** of homomorphisms out of `?` is Theorem 6.9 (`
    nonempty_algHom_of_continuousOnMaps`);
* **uniqueness** is the `?_n = i_n comp j_n` projection-chain argument: `T(?_n) = ?_n+_1` (
    monotone on
    domains), `?_n ?_n = I_?`, and any homomorphism `h` is `?_n h comp ?_n`, the least fixed
    point of
    `fun h. k comp T(h)`.

## The carrier-type subtlety

```

The abstract ``T : Endofunctor DomainObj`` need not preserve token types, so ``T?({Gamma})`` a priori live over different carriers. The hypothesis ``{Gamma} ? T({Gamma})`` already pins ``T({Gamma})`` to ``Gamma``'s carrier, and

monotone on domains (Definition 6.13, ``MonotoneAt.carrier_eq``) propagates the identification up the tower. We carry the carrier equalities explicitly and transport along them; the transport of the subdomain relation is the choice-free ``subsystem_cast``.

Lean note: ``rw`` fragility on defeq-but-not-syntactic implicits

Throughout the uniqueness half, ``rw`` with explicit arguments at the ``ApproximableMap`` / ``NeighborhoodSystem`` level repeatedly failed with "did not find an occurrence of the pattern" even when the pattern was visibly present -- because the implicit carriers/systems were `**defeq` but not syntactically equal** (``colim s`` vs ``(colimAlg s).carrier.sys`` vs ``(objColim s).sys``; the abbrev ``objColim`` vs the literal ``<Tok, colim s>``). Three fixes, used throughout ``gcomp_rho_succ`` / ``gcomp_eq``:

- * work at the categorical ``?`` / ``Category.assoc`` level, where the implicits are concrete ``DomainObj`s` rather than systems, so unification has nothing to get stuck on;
- * prefer ``congrArg`` / ``calc`` `**term-mode**` proofs (e.g. ``congrArg (fun x => g.hom ? x) (key_rho s n)``), since ``calc`` bridges adjacent steps by defeq rather than by syntactic match;
- * to rewrite with a lemma whose implicit is pinned to the "wrong" representation (e.g. ``comp_idMap``, whose ``idMap`` arg is tied to ``g.hom``'s domain ``(colimAlg s).carrier.sys``), first bind the fact via a ``have`` stated in the *desired* form (``have e : g.hom.comp (idMap (colim s)) = g.hom := comp_idMap g.hom`` -- the ``have`` unifies by defeq), then ``rw [ <- e ]``.

/-! ### Theorem 6.14 -- the existence half (the canonical solution and its homomorphisms) -/

/-- **Theorem 6.14 (Scott 1981, PRG-19) -- the canonical fixed point.** Under the hypotheses
(continuous on maps, monotone and continuous on domains, with a generating set `{Gamma} ? T({
Gamma})`), the
iterated colimit `? = ?_n T({Gamma})` is a `T`-algebra whose structure map is an isomorphism
`T(?) ~=?` (the identity, since `T(?) = ?`), and there is a homomorphism from `?` into every
`T`-algebra with a strict structure map (Theorem 6.9). This is Scott's *existence* of the
initial
`T`-algebra. -/
theorem exists_algebra_with_hom (s : Setup.{w}) :
  exists A : TAlgebra s.T, Nonempty (Iso (s.T.obj A.carrier) A.carrier) /\
    forall B : TAlgebra s.T, IsStrict B.str -> Nonempty (AlgHom A B) :=
  <colimAlg s, <colimIso s>, fun B hk => nonempty_algHom s B hk>

/-! ### Theorem 6.14 -- the uniqueness half (`T(?_n) = ?_n+_1`, then `g = ?_n g comp ?_n`)

Scott shows homomorphisms out of `?` are unique by showing they are determined on the finite
elements. Concretely, the projection chain `?_n = i_n comp j_n` satisfies `T(?_n) = ?_n+_1`
(because `T` is

```

```

monotone on domains, so it carries the projection pair `i_n, j_n` to `i_{n+1}, j_{n+1}`) and
`?_n ?_n = I_?`. For any homomorphism `g : ? -> E`, the sequence `g_n = g comp ?_n` is then
  **independent
of `g`**: `g_0 = False` (because `g` is strict and `?_0 = False`), and `g_{n+1} = k comp T(
  g_n) comp j` by the
homomorphism square; so `g = ?_n g_n` is forced. -/

/-- In the category of domains, `?` (categorical composition) is `ApproximableMap.comp`. -/

# Lecture VI -- Lemma 6.15 (Scott 1981, PRG-19): the converse of Proposition 6.12

Proposition 6.12 says a subdomain relation `D ? E` yields a *projection pair* `i : D -> E`,
`j : E -> D` with `j comp i = I_D` and `i comp j subseq I_E`. Lemma 6.15 is the
    converse: any projection
pair -- between two neighbourhood systems `D` and `E` over possibly different token types
--
exhibits `D` as (isomorphic to) a subdomain of `E`. Scott writes `D ? E` as short for "`D ~=
    D'"
for some `D' ? E`."

Lemma 6.15. If there exist approximable maps `i : D -> E` and `j : E -> D` with `j
    comp i = I_D`
and `i comp j subseq I_E`, then `D ? E`.

## The construction (cleaner than Scott's, fully relational)

Scott's proof works with the ideal elements (filters) and shows that `i` carries finite (
    principal)
elements to finite elements. We avoid the filter-by-filter argument by isolating one relational
    predicate:

`IsGen i j X Y := X i Y /\ Y j X` ("Y generates `i(X)`").

Everything follows from three relational facts:

* isGen_exists (uses `j comp i = I_D`): every `X` in `D` has a generator `Y` (apply `j
    comp i = I` to the
identity relation `X I_D X`).

```

```

* **`isGen_mono`** (uses `j comp i = I_D`) and **`isGen_mono'`** (uses `i comp j subseq
  I_E`): the generator
  correspondence is inclusion-monotone in both directions -- `Y subseq Y' <-> X subseq
  X'`. Their two-way use
  gives that generators are unique in each argument (`isGen_fst_unique`/`isGen_snd_unique`).
* **`isGen_inter`** (just `mono`/`inter_right` of `i, j`): if `Y, Y'` are generators and `Y I
  Y' in E`,
  then `Y I Y'` generates `X I X'`.

```

The image system `Dprime i j` has `Y` as a neighbourhood iff `Y` generates some `X` in `D`; its master is `E`'s master. `isGen\_inter` makes it a neighbourhood system **and** gives the crucial `inter\_closed` clause of `?` (consistency inherited from `E`), so `Dprime i j ? E`. The order-isomorphism `D ~ Dprime i j` is `x |-> {Y ? exists X in x, IsGen i j X Y}` with inverse `y |-> {X ? exists Y in y, IsGen i j X Y}`, the inverse laws and order-reflection coming from generator uniqueness.

Everything is built at the level of Definition 2.1 relations, so the whole development is **choice-free** (`#print axioms subseq {proptext, Quot.sound}`).

# Lecture VI -- Theorem 6.16 (Scott 1981, PRG-19): an initial algebra embeds in every solution

> THEOREM 6.16. If on the category of domains and strict approximable maps the functor `T`
  is
> continuous on maps, and if `D` is an initial `T`-algebra, then for any system `E`  $\approx T(E)$ 
  we have
> `D`  $\approx E$ .

Scott's proof. By Theorem 6.9 there is a homomorphism `h : D -> E` and (running 6.9 the other
way) a
homomorphism `g : E -> D`. The composite `g`  $\circ$  `h : D -> D` is a homomorphism of the *
initial* algebra
`D`, hence equals `I_D` by uniqueness. By Lemma 6.15 it remains to show `h`  $\circ$  `g`  $\sqsubseteq$  `I_E`.

Writing `i : T(D) -> D`, `j : D -> T(D)` for `D`'s isomorphism (Lambek, Proposition 6.7)
and
`u : T(E) -> E`, `v : E -> T(E)` for `E`'s, the proof of 6.9 produces `h` and `g` as the
least fixed
points of
`h = u`  $\circ$  `T(h)`  $\circ$  `j` and `g = i`  $\circ$  `T(g)`  $\circ$  `v`.
Setting `h_0 = False`, `g_0 = False` and `h_{n+1} = u`  $\circ$  `T(h_n)`  $\circ$  `j`, `g_{n+1} = i`
 $\circ$  `T(g_n)`  $\circ$  `v`, one computes
`h_{n+1}`  $\circ$  `g_{n+1} = u`  $\circ$  `T(h_n`  $\circ$  `g_n)`  $\circ$  `v` (using `j`  $\circ$  `i = I_{T(D)}`),
so `k_n := h_n`  $\circ$  `g_n` is the approximant
chain of the operator `k |> u`  $\circ$  `T(k)`  $\circ$  `v`. Therefore `h`  $\circ$  `g` =  $\sqsup_n$  `(h_n`
 $\circ$  `g_n)` is its *least* fixed
point, and since `I_E` is a fixed point of that operator, `h`  $\circ$  `g`  $\sqsubseteq$  `I_E`.

## What the formalization does

Everything reuses Theorem 6.9's operator `(homOp T D E j k)`  $\circ$  `?` on Scott's strict
function
space `(D -> False E)` (Exercise 5.10). The per-step computation is isolated as `opStep`. The
three
approximant chains `H`, `G`, `K` (for `h`, `g`, `k`) and the ladder identity `H n`  $\circ$  `G n` =
`K n` give
`h`  $\circ$  `g` = `k` (the least fixed point of `u`  $\circ$  `T(*)`  $\circ$  `v`), which is  $\sqsubseteq$  `I_E`
because `I_E` is a fixed
point. Lemma 6.15 (trianglelefteq_of_projectionPair) then closes `D`  $\approx$  `E`.

# Exercise 6.17 (Scott 1981, PRG-19, S6) -- the algebras for which `C` is initial

> **EXERCISE 6.17.** What are the algebras for which `C` is initial? If `A` of 6.2 is a
  generalization
> of `B`, what is the corresponding generalization of `C`? Prove that it exists and explain
  what are
> the algebras involved.

`C` (Example 4.4: finite-or-infinite binary sequences) satisfies the domain equation
`C` ~={ {?} } + C + C` (Example 6.2, `Example62C.lean`). So `C` is a solution of the domain
equation for
the functor

`T(X) = ? + X + X` (one terminator + two successor copies).

This module proves that **`C` is the *initial* `T`-algebra**: for every `T`-algebra `(E, k)`
there is a
*unique* homomorphism `C -> E`. Concretely a `T`-algebra is a strict map `k : ? + E + E ->
E`, which by
the universal property of the separated sum is the same data as

* a distinguished element `e` in `|E|` (the image of the terminator `?`), and
* two strict endomaps `f_0, f_1 : E -> E` (the two successor branches);

```

```

so the algebras for which `C` is initial are the domains carrying a point and two strict
    unary
operations, and the unique homomorphism `C -> E` interprets a finite-or-infinite binary
    sequence
`b_0b_1b_2...` as `f_{b_0}(f_{b_1}(... e ...))`.

## Why a bespoke category of `{}`-free domains

Scott's separated sum `?_0 + ?_1` (Exercise 3.18) is a neighbourhood system only under the
    standing
assumption `{}` notin ?` (an empty neighbourhood of one summand would become a spurious
    consistency witness
for the other tag, breaking `inter_mem`). Consequently the functor `T(X) = ? + X + X` does not
    extend to a total endofunctor of the all-systems category `DomainObj`, and the existence
    Theorem 6.14
(stated over `DomainObj`) cannot be instantiated directly.

Following Scott -- who restricts to the category of `{}`-free systems and strict maps in
    Exercise 6.19
-- we instantiate the abstract categorical vocabulary (Definitions 6.3-6.5) on the bespoke
    object type
`StrictDomainObj` of neighbourhood systems with no empty neighbourhood, with strict
    approximable
maps as morphisms. The functor `T` then reuses the existing `sum3` (Example 6.2, the genuine
    three-way separated sum) and a three-way sum map, and initiality of `C` is proved directly
    (we
construct the homomorphism and prove its uniqueness by the finite-approximant argument), rather
    than
routing through the colimit construction of Theorem 6.14.

Everything is choice-free where it is data; the homomorphism/uniqueness layer reuses the
    project's
established machinery.

# Exercise 6.17 part 2 (Scott 1981, PRG-19) -- the generalization `C? ~?= ? + Sigma? C?`

Example 6.2 / Exercise 6.17 ask for the generalization of `C` corresponding to Scott's `A ~?= A? + A?`:
replace the two-letter alphabet `{0,1}` of `C` (`C ~?= ? + C + C`) by an arbitrary alphabet `A`. The
domain `C?` of *finite or infinite `A`-sequences* then satisfies the domain equation
`C? ~?= ? + Sigma_{a:A} C?` (the `A`-indexed separated sum of copies of `C?`). Instantiating `
A := Fin n`
gives **`C_n ~?= ? + n*C_n`**; `A := Bool` recovers Example 6.2's `C`.

This module mirrors, generically over an alphabet `A` with decidable equality, the binary
development
of `Example44` (the domain), `Example62`/`Example62C` (the sum and the isomorphism) and `
Exercise617`
(initiality).

## Stage 1 (this section): the generic domain `C?`

```

```

`Strn A = List A`; cones `coneN sigma = sigmaA*`; the neighbourhood system `Cn = {sigmaA*} U
  {{sigma}}`; the total
elements `strElemN sigma` and partial elements `strBotN sigma`; and the successors `consMapN a
  : C? -> C?`
prepending the letter `a`. Everything is the alphabet-generic copy of `Example44`, and the data
(`Cn`, `consMapN`) stays choice-free.

# Exercise 6.18 (Scott 1981, PRG-19, S6) -- `?^inf` as an initial algebra

> **EXERCISE 6.18.** With reference back to Exercise 3.16 discuss the construction of `?^inf`
  as an
> initial algebra and as a solution to the domain equation `?^inf ~?= ? x ?^inf`.

```

Exercise 3.16 already constructs the infinite iterate $\text{?}^\infty \text{?}$ (`iterSys``, over $\text{Nat} \times \Delta$) and proves the

****domain-equation**** $\text{half}, \text{?}^\infty \text{?} \sim \text{?} \times \text{?}^\infty \text{?}$ (`iter_isomorphic``, with the explicit element `iso` `iterProdIso``). This module supplies the ****initial-algebra**** `half`.

For a fixed $\{\}$ -free domain ? consider the (product) endofunctor $T(X) = \text{?} \times X$. The domain equation $\text{?}^\infty \text{?} \sim T(\text{?}^\infty \text{?})$ makes $\text{?}^\infty \text{?}$ a T -algebra, with structure map

$\text{?} : \text{?} \times \text{?}^\infty \text{?} \rightarrow \text{?}^\infty \text{?}$ the "cons" isomorphism (Exercise 3.16's `iterProdIso-1`). We prove ****?[∞] is the initial T-algebra****: for every T -algebra (E, k) there is a *unique* (strict) homomorphism $\text{?}^\infty \text{?} \rightarrow E$, namely $\text{h}(\langle x_0, x_1, \dots \rangle) = k(x_0, k(x_1, k(x_2, \dots)))$, the least fixed point of

$\text{fun } h. k \text{ comp } T(h) \text{ comp } j$.

Architecture

The genuine analysis is done at the level of plain approximable maps (over `iterSys V``, `prod V (iterSys V)``, and a target `E``), then packaged into the bespoke category `StrictDomainObj`` of $\{\}$ -free domains and strict maps (Exercise 6.17), where `IsInitial`` directly expresses Scott's universal property among strict algebras (cf. Theorem 6.14, which is initiality *among strict algebras* -- the product functor grows the token set, so Theorem 6.14's same-carrier colimit tower does ****not**** apply, and $\text{?}^\infty \text{?}$ must be built directly as in Exercise 3.16).

****Existence.**** `descMap = ?_n h_n``, `h_0 = False``, `h_{n+1} = k comp T(h_n) comp j``. It is strict and satisfies the fixed-point equation `descMap = k comp T(descMap) comp j``, hence the homomorphism square `descMap comp i = k comp T(descMap)`` (since `j comp i = I``).

****Uniqueness.**** The truncation chain $\text{?}_n : \text{?}^\infty \text{?} \rightarrow \text{?}^\infty \text{?}$, `?_0 = False``, `?_{n+1} = i comp T(?_n) comp j``, computes to $\text{?}_n(\langle x_i \rangle) = \langle x_0, \dots, x_{n-1}, \text{False}, \text{False}, \dots \rangle$ (`rho_apply``) and satisfies  $\text{?}_n \text{?} = I$  (`iSupRho_eq_id``, the cofinite- Δ structure of `iterSys``). For any strict homomorphism `g``, the sequence $g \text{ comp } ?_n$ is `g``-independent (the recursion `g comp ?_{n+1} = k comp T(g comp ?_n) comp j``), so $g = ?_n g \text{ comp } ?_n$ is forced.

Everything is choice-free where it is data.

# Exercise 6.19 (Scott 1981, PRG-19, S6) -- sum and product on the category of strict maps

> **EXERCISE 6.19.** For the sake of uniformity restrict attention to systems  $\mathcal{T}$  on sets
>  $\Delta \text{ subseteq } \{0,1\}^*$ , where  $\mathcal{T}$  in  $\Delta$  and  $\{\}$  notin  $\mathcal{T}$ , and to the category of
  strict maps. Define sum and
> product by
>  $\mathcal{T}_0 + \mathcal{T}_1 = \{\{\mathcal{T}\} \cup 0\Delta_0 \cup 1\Delta_1\} \cup \{0X \mid X \text{ in } \mathcal{T}_0\} \cup \{1Y \mid Y \text{ in } \mathcal{T}_1\}$ ,
>  $\mathcal{T}_0 \times \mathcal{T}_1 = \{\{\mathcal{T}\} \cup 0X \cup 1Y \mid X \text{ in } \mathcal{T}_0 \text{ and } Y \text{ in } \mathcal{T}_1\}$ .
> Are these correct up to isomorphism? ...

This module formalizes **Part A** of the exercise: Scott's *uniform* token-level presentations
of
sum and product over  $\{0,1\}^*$  (so that the constructions are genuine *endo*-operations on a
single
category, unlike the abstract separated sum  $\mathcal{T}_0 + \mathcal{T}_1$  of Exercise 3.18 over  $\text{Option } (a \times b)$ 
or the

```

product $\prod_{i=0}^n x_i$ of Definition 3.1 over $\{a, b\}$), and the answer to "Are these correct up to isomorphism?" -- **yes**:

* $\text{sumTok_iso_sum} : \text{sumTok } D_0 D_1 h_0 h_1 \sim = ? \text{ sum } D_0 D_1 h_0 h_1$, and
 * $\text{prodTok_iso_prod} : \text{prodTok } D_0 D_1 \sim = ? \text{ prod } D_0 D_1$.

We reuse the single-bit prefix $\text{embBit } b \ X = bX$ of Example 6.2 (so $0X = \text{embBit false } X$, $1Y = \text{embBit true } Y$), whose disjointness/intersection algebra (embBit_inter , embBit_inter_ne , embBit_subset , embBit_injective , embBit_nonempty) is exactly what makes the concrete sum $\sum_a$ neighbourhood system and drives the isomorphism (a token-level analogue of Example62.bbEquiv , generalised from B to arbitrary $\{0,1\}$ -free D_0, D_1).

The functor-algebra closure (all $T(X)$ generated by constants/identity/sum/product are functors, continuous on maps, monotone and continuous on domains) is **Part B**, deferred.

Everything here is **choice-free** ($\# \text{print axioms subseteq \{proptext, Quot.sound\}}$).

# Exercise 6.19 (Scott 1981, PRG-19, S6) -- Part B: the functor algebra

> ... Now generate all constructs `T(X)` formed by the constants (that is, `T(X) = ?` for a
    fixed `?`),
> by the identity (`T(X) = X`), and by sums and products (`T_0(X) + T_1(X)`, etc.). Show that
    these are
> all functors, continuous on maps, and monotone and continuous on domains.

This module formalizes Part B: the closed family of constructs `T(X)` over Scott's uniform
*
category of Exercise 6.19 -- neighbourhood systems on `Delta` subseqeq `{0,1}*` with `{}` notin
`?` (the standing
hypothesis that makes the token-level sum `sumTok`/product `prodTok` of Part A genuine
*endo*-operations) and strict approximable maps.

## Contents

* `ScottSys` -- an object of Scott's category: an `{}`-free neighbourhood system over `Str =
  {0,1}*`.
* The object actions `ScottSys.sum`/`ScottSys.prod` (Part A's `sumTok`/`prodTok`, repackaged so
  they
  stay inside the category) and the constant/identity objects.
* The functorial action on maps*: `sumMapTok f_0 f_1 : (?_0+?_1) -> (?_0+?_1)` and
  `prodMapTok f_0 f_1 : (?_0 x ?_1) -> (?_0 x ?_1)`, each an approximable map, with
  strictness preservation
  (`sumMapTok` is always strict; `prodMapTok` is strict when both factors are).
* The bifunctor laws: both actions preserve identities and composition
  (`sumMapTok_id`/`sumMapTok_comp`, `prodMapTok_id`/`prodMapTok_comp`).
* The functor-expression algebra `FExpr` (constants, identity, sum, product), its object action
  `FExpr.obj`, its action on maps `FExpr.map`.

```

Scott asks to show these constructs are **all** functors, continuous on maps, and monotone and continuous on domains; each is established here:

```
* **functors** -- `FExpr.map_id` (`T(I)=I`) and `FExpr.map_comp` (`T(g comp f)=T(g) comp T(f)`)
  , by induction;
  plus `FExpr.map_isStrict` (so `T` restricts to Scott's strict-map category).
* **continuous on maps** -- `FExpr.map_mono` (a sharper map gives a sharper image) and
  `FExpr.map_continuous` (`fun f. T(f)` preserves directed unions of maps); together these are
  exactly
  approximability of `fun f. T(f)` (Exercise 2.13).
* **monotone on domains** -- `FExpr.obj_subsystem` (`D ? E ? T(D) ? T(E)`).
* **continuous on domains** -- `FExpr.obj_continuous` (`fun D. T(D)` preserves directed unions
  of
  subsystems, the form Scott uses in Theorem 6.14).
```

Because every construct stays over the single token type $\{0,1\}^*$, the subdomain relation $\preceq$ is between systems on a common carrier, so the domain conditions need no carrier transport (unlike the universe-polymorphic `Endofunctor DomainObj` form of Definitions 6.8/6.13).

This module also formalizes **Exercise 6.20**: writing `tok(?) = ?.master` for the underlying token set and `{Gamma}` for the one-neighbourhood system `singletonSys Gamma`, the function `fun Gamma. tok(T({Gamma}))` is computed by the token-level recursion `mFun T` (`mFun_eq_master`)`, shown monotone (`mFun_mono``) and continuous (`mFun_continuous``) on the domain `{Gamma ? ? in Gamma}`. Its least fixed point -- the explicit Kleene union `?_n mFun?({?})` -- gives a Gamma = tok(T({Gamma}))` (exists_tok_fixedPoint`), whence {Gamma} ? T({Gamma})` (exists_singleton_subsystem`), exactly the hypothesis Theorem 6.14 needs.`

Everything is **choice-free** (`#print axioms subseq {proptext, Quot.sound}`).`

/-! ## Exercise 6.20 -- `fun Gamma. tok(T({Gamma}))` is continuous, hence a fixed point exists

> For any system `?` let `tok(?)` be the underlying set of tokens, so that `?` is a system over
> `tok(?)`. For the category of Exercise 6.19 show that the function `fun Gamma. tok(T({Gamma})
> )` is continuous
> on the domain `{Gamma subseq {0,1}* ?? in Gamma}`, where `T` is any of the functors
  generated in 6.19. Conclude
> that there must exist a set `Gamma = tok(T({Gamma}))`, so that `{Gamma} ? T({Gamma})`, and so
  6.14 applies.

Here `tok(?) = ?.master` (the master neighbourhood *is* the token set `Delta`, since `?`
  subseq (Delta)), and
`{Gamma}` is the one-neighbourhood system `singletonSys Gamma` with master `Gamma`. The key
  simplification is
that the *master* of `T({Gamma})` is computed by a tiny token-level recursion `mFun T` that
  needs no
`NeighborhoodSystem` data at all: constants are constant, the identity returns `Gamma`, and **
  both** sum
and product return `{?} U 0*(...) U 1*(...)`. (`sumTokMaster = prodTokNbhd` on masters). `
  mFun_eq_master`
identifies `mFun T Gamma` with `tok(T({Gamma}))`. The function `mFun T` is monotone (`mFun_mono
  `) and
continuous -- in fact fully additive -- on the powerset of `{0,1}*` (`mFun_continuous`), so its
  restriction to `{Gamma ?? in Gamma}` is continuous on that domain. The least fixed point
  above the bottom
`{?}` is the explicit Kleene union `?_n mFun?({?})` (`mIter`), giving `Gamma = tok(T({Gamma}))`
  (`exists_tok_fixedPoint`) and hence `{Gamma} ? T({Gamma})` (`exists_singleton_subsystem`),
  exactly the
hypothesis Theorem 6.14 needs. (For the bottom to stay in the domain we need `?` in `tok(C)`
  for the
constant systems `C`; this is recorded by `FExpr.RootedConst`, and holds automatically for sums
  and
products since their masters contain `?`.) -/

/-- **`tok(?)`** -- the underlying set of tokens of a system, i.e. its master neighbourhood `
  Delta`. -/

# Exercise 6.21 (Scott 1981, PRG-19, S6) -- the *separated* sum `?` and product `?`

> **EXERCISE 6.21.** Do the same as 6.19 and 6.20 when the functors are also allowed to be
  generated
> by the operations
> `D_0 ? D_1 = {{?} U ODelta_0 U 1Delta_1} U {OX ? X in D_0 ? {Delta_0}} U {1Y ? Y
  in D_1 ? {Delta_1}}`,
> `D_0 ? D_1 = {{?} U ODelta_0 U 1Delta_1} U {{?} U OX U 1Y ? X in D_0 ? {Delta_0}
  and Y in D_1 ? {Delta_1}}`.
> Generalize all of `+`, `x`, `?`, `?` to combinations of several terms, not just the binary
  sums and
> products.

This module extends Exercise 6.19 Part B (`Exercise619PartB.lean`) with the two *coalesced*
operations. The difference from the *separated* sum `+`/product `x` of 6.19 is that `?`/`?`
**delete
the improper tagged copies** `ODelta_0` and `1Delta_1`: in domain terms this **identifies the
two bottoms**
(`?` is the coalesced sum, `?` the smash product), whereas `+`/`x` keep them apart. Both
share the
*same master* `{?} U ODelta_0 U 1Delta_1` as `+`/`x`.

## Contents (this stage: objects)

* `oplusTok`/`otimesTok` -- the two token-level systems over `Str = {0,1}*`, each `{}`-free.
* `ScottSys.oplus`/`ScottSys.otimes` -- the same, repackaged as objects of Scott's category.

Everything is **choice-free** (`#print axioms subseq {propeq, Quot.sound}`).

/-! ## The functorial action of the coalesced sum on (strict) maps

The relation has the same shape as `sumMapTok` but with two changes forced by *coalescence*:
  proper
tagged copies require the components to be proper (`X != Delta_0`, `X' != Delta_0'`), and
  the **master/collapse
row** `(W in ?_0??_1 /\ W' = M)` sends *every* neighbourhood to the top `M` (which is
  always valid, the
top being the least informative output, and is exactly what handles `f_0(X) = Delta_0'`
  collapsing back to
the shared bottom). -/

/-! ## The extended functor-expression algebra `GExpr`

Scott's *do the same as 6.19 and 6.20 when the functors are also allowed to be generated by
the
operations `?`, `?`*: the closed family of constructs is enlarged from `FExpr` (constants,
identity, `+`, `x`) to also include the coalesced `?` and the smash `?`. The functor laws and
the
on-maps/on-domains continuity properties are re-established by induction; the `?`/`?`
composition
law carries the strictness hypothesis (Scott's category is the strict-map category, and
that is
exactly what makes `?`/`?` functorial). -/

/-- **The extended functor-expression algebra** (constants, identity, `+`, `x`, `?`, `?`). -/

/-! ## Exercise 6.20 for the extended algebra -- `fun Gamma. tok(T({Gamma}))` is continuous, so
  a fixed point
exists
```

The masters of ?/? coincide with those of +/? $\times$ (all four equal $\text{?} \cup \text{O}\Delta_0 \cup 1$ Δ_1), so the token-level recursion gFun has the **same** tagged-union body in all four binary cases. The 6.20 argument (continuity of $\text{fun Gamma. tok(T(\{Gamma\}))}$ and existence of $\text{Gamma} = \text{tok(T(\{Gamma\}))}$, whence $\text{\{Gamma\} ? T(\{Gamma\})}$ and Theorem 6.14 applies) goes through verbatim, reusing the generic helpers singletonSys , insertTag_mono , $\text{insertTag_continuous}$ of Exercise 6.19 Part B. -/

```

/-! ## Generalizing `+`, `x`, `?`, `?` to combinations of several terms

> Generalize all of `+`, `x`, `?`, `?` to combinations of several terms, not just the binary
  sums
> and products.

Because `GExpr` is **closed** under the binary operations, every finite combination of several
  terms
`T_0 ? T_1 ? ? ? T_n` (for any `?` in `{+, x, ?, ?}`, in any nesting) is itself a `GExpr` --
  so the
results already proved (`map_id`, `map_comp`, `map_mono`, `map_continuous`, `obj_subsystem`,
`obj_continuous`, and the 6.20 fixed point `gExists_singleton_subsystem`) apply to *all* of
  them with
no further work. The `naryOp` fold below packages the common right-nested n-ary constructs
`?(a, [b, c, ...]) = a ? (b ? (c ? ?))` explicitly, and `naryOp_rootedConst` shows the `?` in
  tok`

```

```

side-condition (needed for the 6.20 fixed point) is preserved, so every n-ary construct also
  has a
solution `Gamma = tok(T({Gamma}))`. -/

# Exercise 6.22 (Scott 1981, PRG-19, S6) -- commenting on three domain equations

> **EXERCISE 6.22.** Comment on these domain equations:
> `N  ~=  {{0}, {0, ?}} ? N`,
> `M  ~=  {{?}} + M`,
> `N* ~=  N ? (N ? N*)`.

This is a "comment on" exercise, so the substantive formal content is to recognise each
equation as
an instance of the fixed-point machinery built in Exercises 6.19–6.21. Every right-hand side is
a
construct `T(X)` of the algebra `GExpr` (constants, identity, `+`, `x`, `?`, `?`), whose
constants are
**rooted** (contain `?`). Hence by `gExists_singleton_subsystem` (Exercise 6.21/6.20) there is
a token
set `Gamma` with `Gamma = tok(T({Gamma}))`, so `{Gamma} ? T({Gamma})` and **Theorem 6.14
applies**: each equation has a
solution.

## What the three domains *are* (the "comment")

* `N  ~=  {{0},{0,?}} ? N`. The constant `{0},{0,?}` is the **two-point domain** (a chain
`{0} ? Delta`,
i.e. one proper point above the bottom). Folding it under the **coalesced** sum `?` -- which
*identifies* the bottoms at each stage -- stacks the proper points into a single chain. So `N`
is the
domain of **vertical natural numbers**: a chain `False sqsub 0 sqsub 1 sqsub ?` topped
by a limit `inf`.
* `M  ~=  {{?}} + M`. The constant `{?}` is the **one-point domain** `?` (the terminal object
). Folding
it under the **separated** sum `+` -- which keeps the two bottoms *apart*, offering a genuine
stop/continue choice at each step -- yields the **lazy natural numbers**: each `n` is a
distinct
partial element `succ?(stop)`, with `False` below every finite stage and one infinite element
. The only
difference from `N` is coalesced vs. separated: `?` collapses the choice into a chain, `+`
keeps it
branching.
* `N* ~=  N ? (N ? N*)`. With the **smash** product `?` (strict pairing: a pair is `False`
unless *both*
coordinates are proper) and the coalesced `?`, this is the cons-cell equation `X  ~=  N ? (N
? X)`: an
```

```

element is either a single datum from `N` or a strict head/tail pair. So `N*` is the domain
of
**finite and infinite strict sequences (streams) over `N`**.

All three solutions are obtained uniformly below; the only per-equation work is exhibiting the
constant systems `{0},{0,?}`, `{?}` and checking they are `{}`-free and rooted. Everything
is
**choice-free** (`#print axioms subseteq {propext, Quot.sound}`).

Exercise 6.23 (Scott 1981, PRG-19, S6) -- the syntactic domain of expressions

> ****EXERCISE 6.23.**** Construe the initial solution to

> $\text{Exp} \approx N ? ((\text{Exp} \times \text{Exp}) + (\text{Exp} \times \text{Exp}))$

> as a "syntactical domain" of expressions generated from infinitely many "variables" by means of two

> binary "operation symbols". Given an algebra D with two operations $u : D \times D \rightarrow D$ and

> $v : D \times D \rightarrow D$, show how any strict map $s : N \rightarrow D$ determines a unique map $\text{val}(s) : \text{Exp} \rightarrow D$ that

> can be regarded as the "evaluation of an expression".

The right-hand functor is $T(X) = N ? ((X \times X) + (X \times X))$, i.e. in the algebra GExpr of Exercise 6.21,

$\text{Tex}p\ N = .oplus (.const\ N) (.sum (.prod .var .var) (.prod .var .var))$. Reading the structure map

$k : T(\text{Exp}) \rightarrow \text{Exp}$ of an algebra through the universal properties of $?$, $+$, $\times$:

* the N summand gives a strict ****variable map**** $s : N \rightarrow \text{Exp}$ (the "infinitely many variables"

are the tokens / points of N);

* the two $(\text{Exp} \times \text{Exp})$ summands, combined by $+$, give two binary ****operation symbols**** $u, v : \text{Exp} \times \text{Exp} \rightarrow \text{Exp}$.

So an algebra of this functor is exactly ****a domain** D with a strict $s : N \rightarrow D$ and two binary

operations $u, v : D \times D \rightarrow D$, and the unique homomorphism $\text{val}(s) : \text{Exp} \rightarrow D$ is Scott's "evaluation

of an expression": it sends a variable to its value under s , and an u/v -node to the u/v of

the values of its two subexpressions.

This module (Phase 1 -- the domain Exp itself)

Following Scott's standing restriction in Exercises 6.19-6.23 to $\{\}$ -free systems over $\{0,1\}^*$ and

****strict* maps** (ScottSys), and following the structure of ****Theorem 6.14**** (the initial solution is

the iterated colimit $? = ?_n T(\{\Gamma\})$, we build the concrete solution domain ****for any rooted**

GExpr functor** T :

* $\text{gFix } T = ?_n \text{gFun}(\{\Gamma\})$ -- the token set (Exercise 6.20/6.21 fixed point $\Gamma = \text{tok}(T(\{\Gamma\}))$);

* $\text{gTower } T\ n = T(\{\Gamma\})$ -- the iterated-functor tower of $\{\}$ -free systems over Str ;

* $\text{gColim } T = ?_n T(\{\Gamma\})$ -- the colimit system, with $\text{gColim_obj_eq} : T(\text{gColim}) = \text{gColim}$ (the

structure map is the ****identity****, since the two systems are literally equal -- no carrier transport

is needed because ScottSys keeps the token type fixed at Str).

Instantiating at $\text{Tex}p\ N$ gives $\text{Exp } N := \text{gColim } (\text{Tex}p\ N)$ together with the domain-equation ****isomorphism**** $\text{Exp} \approx N ? ((\text{Exp} \times \text{Exp}) + (\text{Exp} \times \text{Exp}))$ (Exp_structure_eq). The algebra decomposition

(s , u , v) and the unique evaluation homomorphism $\text{val}(s)$ (initiality) are developed in

```

    later
phases.

Everything is choice-free (#print axioms subseteq {propext, Quot.sound}); the colimit
    is genuine data
built without Classical.choice (the generator Gamma is the explicit Kleene union, not an
    existential witness).

/-! ## Phase 2 -- the strict-map category, the endofunctor `T`, and the algebra `Exp`

Following Scott (and Exercise 6.17's `StrictDomainObj`), but over the *fixed* token type `Str`:
the
objects are `ScottSys` ({}-free systems over `Str`), the morphisms are **strict** approximable
maps.
Because every object lives over `Str`, all carrier equalities are `rfl` and there is no `HEq`
transport (the obstruction that made the abstract Theorem 6.14 unusable). The functor `Texp N`
then
becomes a genuine `Endofunctor` of this category, and the colimit `Exp` of Phase 1 -- together
with the
structure equality `T(Exp) = Exp` -- is a `T`-algebra. -/

/-- **The category of `{}`-free domains over `Str` and strict maps.** Morphisms are strict
approximable
maps (`StrictMap`); identities and associative composition are Theorem 2.5, with strictness
preserved
by `isStrict_idMap`/`isStrict_comp`. The fixed carrier `Str` is what removes all the carrier-
transport
`HEq` that burdens the abstract `Endofunctor DomainObj`. -/

/-! ## Phase 3 -- the evaluation homomorphism `val(s)` (existence)

Given any algebra `B = (D, k)` of `T(X) = N ? ((X x X)+(X x X))` -- i.e. a domain `D` carrying
(through the
universal properties of `?`,`+`,` x `) a strict variable map `s : N -> D` and two binary
operations
`u, v : D x D -> D` -- we build a `T`-algebra homomorphism `val : Exp -> D`. This is Scott's
s *"evaluation
of an expression"*.

Since Phase 1's structure map `i : T(Exp) -> Exp` is the **identity** (`Exp_structure_eq`),
the
homomorphism equation `val comp i = k comp T(val)` is the fixed-point equation `val = k
comp T(val) comp j`
(`j = i^-1`). We solve it directly by the Kleene iteration `val_n` (`val_0 = False`,
`val_n+1 = k comp T(val_n) comp j`) and take `val = ?_n val_n`. The fixed-point property
uses *continuity on
maps* (`GExpr.map_continuous`: `T(? val_n) = ? T(val_n)`); no projection machinery is needed
for
existence. (Uniqueness -- initiality -- is the remaining Phase 4.) -/

/-! ## Phase 4 -- uniqueness of `val(s)` and initiality of `Exp`

Scott proves homomorphisms out of the iterated colimit are unique by showing they are *
determined on
the finite elements*: the projection chain `?_n = i_n comp j_n` (Proposition 6.12's pair for
`Texp?({Gamma}) ? Exp`) satisfies `T(?_n) = ?_n+_1` and `?_n ?_n = I_Exp`, so any homomorphism
`g` equals
`?_n g comp ?_n`, a sequence that is forced by the recursion (independent of `g`). The crux
is the
*concrete* "monotone on domains" content (Definition 6.13): the functor `Texp` carries the
canonical
6.12 projection pair of `D ? E` to that of `T(D) ? T(E)` -- here a genuine **equality** of maps
over
`Str` (no `HEq` carrier transport, the whole point of staying in `ScottSys`).

This section establishes that crux as `GExpr.map_inj`/`GExpr.map_proj` (by induction over the
six
functor constructors), then mirrors Theorem 6.14's uniqueness argument concretely. -/

/-! ### Proposition 6.12 helpers: the projection pair is strict, and trivial on `D ? D` -/

/-- The injection `i : D -> E` of a subsystem is **strict**: `i` sends `Delta_D` only to `
Delta_E`. -/

/-! ### The crux (Definition 6.13, concrete): `T` carries the 6.12 projection pair

This is the *monotone on domains* content of Definition 6.13, but here a genuine **equality**
of maps
over the single token type `Str` (no `HEq` carrier transport): the functor `T = GExpr` sends
the
injection/projection of `D ? E` to the injection/projection of `T(D) ? T(E)`. Proved by
induction
over the six constructors using the token-level lemmas just established. -/

```

```

/-- **`T(i) = i`** -- the functor carries the injection of `D ? E` to that of `T(D) ? T(E)`.
-/

# Exercise 6.24 (Scott 1981, PRG-19, S6) -- a double fixed point for a system of domain
equations

> **EXERCISE 6.24.** Show that there must exist domains satisfying
> `D ~ D + (D x E)` and `E ~ D + E`,
> by using a double fixed-point method. First decide what the underlying set of tokens should
be, and
> then define `D` and `E` by simultaneous fixed points. (Syntactical domains as in 6.23 may
very well
> require several simultaneous equations.)

This is the simultaneous analogue of Exercise 6.20/6.21: there the conclusion was a single
`Gamma` with `Gamma = tok(T({Gamma}))`, so that `{Gamma} ? T({Gamma})` and Theorem 6.14 applies
; here we produce a
**pair** `(Gamma_D, Gamma_E)` of token sets that solve the two coupled token equations
**simultaneously**, so that the two singleton systems sit as subsystems of the two right-hand
sides
at once -- exactly the joint hypothesis the simultaneous form of Theorem 6.14 needs.

## Deciding the tokens

Both `D` and `E` are taken to be `{}`-free neighbourhood systems over the single token type

```

```

`Str = {0,1}*` (Scott's uniform category of Exercise 6.19). The two right-hand sides are built
from
the uniform sum `+` (`ScottSys.sum`) and product `x` (`ScottSys.prod`), whose *master* (token
set)
is in both cases the tagged union `{?} U 0*(...) U 1*(...)`. Writing `tok(?) = ?.master`
and `{Gamma}` for
the one-neighbourhood system `singletonSys Gamma`, the two token recursions are

* `gTok p q = tok((D + E))`      = `{?} U 0p U 1q` (for `D = {p}`, `E = {q}`),
* `fTok p q = tok((D + (D x E)))` = `{?} U 0p U 1(gTok p q)`,

so `fTok p q = gTok p (gTok p q)` (the product `D x E` and the sum `D + E` have the *same*
tagged
master shape).

## The double fixed point

The pair map `(p, q) = (fTok p q, gTok p q)` is iterated from the bottom pair `({?}, {?})`
(`pIter`); its two component unions

`Gamma_D = ?_n (??)._1`, `Gamma_E = ?_n (??)._2`

solve `fTok Gamma_D Gamma_E = Gamma_D` and `gTok Gamma_D Gamma_E = Gamma_E` (`
fTok_GammaD_GammaE`, `gTok_GammaD_GammaE`).
Both `fTok`/`gTok` are *fully additive* (built from `insert`, `embBit`, `U`), and --
crucially -- every
token of `fTok`/`gTok` references **at most one** of the two coordinates, so each membership is
witnessed at a *single* finite stage (no directedness merge is needed). This is the elementary
token-level continuity that makes the Kleene union a fixed point.

## The conclusion (`{Gamma_D} ? D + (D x E)` and `{Gamma_E} ? D + E`)

Setting `D = {Gamma_D}`, `E = {Gamma_E}`, the fixed-point equations say exactly that `Gamma_D`
(resp. `Gamma_E`) is
the master of `D + (D x E)` (resp. `D + E`), so the singleton systems are subsystems of the two
right-hand sides -- `Dsol_subsystem`, `Esol_subsystem`. These two facts *together* are the
hypotheses
of the simultaneous Theorem 6.14, which then yields the required isomorphisms
`D ~= D + (D x E)` and `E ~= D + E`.

Everything is **choice-free** (`#print axioms subseq {propt, Quot.sound}`).

# Lecture VI -- Exercise 6.25 (Scott 1981, PRG-19): the Galois connection of a projection pair
```

```
**Exercise 6.25.** For a projection pair  $g : \alpha \rightarrow \beta$  and  $h : \beta \rightarrow \alpha$  show that for  $x$  in  $|\alpha|$  and
```

```
 $y$  in  $|\beta|$  we have
```

```
 $g(x) \sqsubseteq y \iff x \sqsubseteq h(y)$ .
```

Thus conclude

```
 $h(y) = \sqsup \{x \mid g(x) \sqsubseteq y\}$  and  $g(x) = \sqcap \{y \mid x \sqsubseteq h(y)\}$ ,
```

so each of the two functions determines the other. Check that the set in the first equation is directed, and that the set in the second is non-empty. Prove also that g maps consistent sets to

consistent sets and **preserves** $\sqsup$ (not just *directed* unions).

```
## Dictionary to the codebase
```

Scott's g is the injection i and his h is the projection j of Proposition 6.12; we

carry

them abstractly in `Subsystem.ProjectionPair` (fields `inj = g`, `proj = h`) together with the

two defining laws

```
* `proj_comp_inj : h ∘ g = I_?` (P.proj.comp P.inj = idMap ?), and
```

```
* `inj_comp_proj_le : g ∘ h ⊆ I_?` (P.inj.comp P.proj ≤ idMap ?).
```

On *elements* (`toElementMap`) these read $h(g(x)) = x$ (`proj_inj_apply`) and $g(h(y)) \sqsubseteq y$

(`inj_proj_apply_le`); everything below is a short consequence of these two facts plus monotonicity

of approximable maps on elements (`toElementMap_mono`).

```
* `galois` -- the adjunction  $g(x) \sqsubseteq y \iff x \sqsubseteq h(y)$ .
```

```
* `proj_eq_sSup` / `lowerSet_directed` --  $h(y) = \sqsup \{x \mid g(x) \sqsubseteq y\}$ ; the set is a down-set of
```

```
 $h(y)$ , hence directed and bounded by  $h(y)$ .
```

```
* `inj_eq_sInf` --  $g(x) = \sqcap \{y \mid x \sqsubseteq h(y)\}$ ; the set is an up-set of  $g(x)$ , hence non-empty
```

```
(it contains  $g(x)$ ).
```

```
* `inj_bounded` --  $g$  maps bounded ("consistent") sets to bounded sets.
```

```
* `inj_sSup` --  $g$  preserves all existing least upper bounds:  $g(\sqsup S) = \sqsup \{g(s) \mid s \in S\}$ .
```

This is the hallmark of a lower adjoint and is the substance of the last sentence of the exercise.

Everything here is **choice-free** (`#print axioms ⊆ {propx, Quot.sound}`): the `sSup`/`sInf` of

Exercises 1.18/1.27 are the only constructions used and are themselves choice-free.

# Exercise 6.26 (Scott 1981, PRG-19, S6) -- the lifting `?_False` over `{0,1}*`

> **EXERCISE 6.26.** For systems `?` as in 6.19 define
> `?_False = {{?} U 0Delta} U {0X ? X in ?}`.
> Describe the construct in terms of elements. Is this a suitable functor? Prove that
> `?_False ? ?_False ~ = ? + ?`. What is `?_False ? ?_False ~ = ??`

The **lifting** `?_False` adds a new bottom below a `0`-tagged copy of `?`. Its master is
`{{?} U 0Delta` and its proper neighbourhoods are the `0X` for `X in ?` (including `0Delta`,
which sits
strictly above the new bottom `{{?} U 0Delta}`). It is the one-summand analogue of Exercise
6.19's sum.

## Contents

* `liftTok`/`ScottSys.lift` -- the lifted system over `Str = {0,1}*`, again `{}`-free.
* **Elements** (`liftBot`, `liftUp`, `unlift`): `|?_False| ~ = |?|_False`. The bottom `liftBot`
  is the fresh
  least element; `liftUp x` embeds `|?|` order-isomorphically above it (`liftBot_lt_liftUp`,
  `liftUp_le_liftUp_iff`); every element is one or the other (`eq_liftBot_or_exists_liftUp`).
* **Functor** (`liftMapTok`, `liftMapTok_isStrict`, `liftMapTok_id`, `liftMapTok_comp`): *yes*,
  `(*)_False`
  is a (strict) functor on Scott's category -- the action on maps preserves identities and
  composition.
* **?_False ? ?_False ~ = ? ? + ?** (`lift_oplus_lift_iso_sum`): coalescing the two fresh
  bottoms of the
  lifts reproduces exactly the separated sum.
* **?_False ? ?_False ~ = ? (? x ?)_False** (`lift_otimes_lift_iso_lift_prod`): the answer
  to Scott's `??` -- the
  smash of two lifts is the lift of the product.

All constructions are **choice-free** (`#print axioms subseq {propeq, Quot.sound}`); the
lone exception

```

```

is `eq_liftBot_or_exists_liftUp`, a `Prop`-level case split that uses excluded middle (`
  Classical`)
to decide whether an element lies above the fresh bottom -- unavoidable and called out there.

/-- **Exercise 6.26 -- `?_False ? ?_False ~=? ? + ?`.** Coalescing the fresh bottoms of the
two lifts
reproduces the separated sum. -/
theorem lift_oplus_lift_iso_sum :
  (D.lift.oplus E.lift).sys ~=? (D.sum E).sys := <sumLiftEquiv>

/-! ## `?_False ? ?_False ~=? (? x ?)_False` -- the answer to Scott's `??`

The smash of the two lifts has proper neighbourhoods `{?} U 0(OX') U 1(OY')` (i.e.
`prodTokNbhd (OX') (OY')`, with `X'` in `?`, `Y'` in `?`). The lift of the product has proper
neighbourhoods `0(prodTokNbhd X' Y')`. The element iso transports one rectangle presentation to
the
other. Unlike the sum there are no cross-tag intersections, so the proof is purely "
rectangular". -/

# Exercise 6.27 (Scott 1981, PRG-19, S6) -- which subsystem relations hold
```

```
> **EXERCISE 6.27.** Which of the following relationships are true:
> `(???) ? (x ?)`; `??? x ?`;
> `(???) ? (+ ?)`; `??? ?`;
> `(? -> False) ? (? -> ?)`; `??? ?` ?
```

Here `?` is Scott's **embeds-as-a-subdomain** relation of Lemma 6.15 (`Trianglelefteq``): ``D ? E`` means ``D ~ = ? D`` for some ``D' ? E``. We use the concrete `{0,1}`* constructions of Exercises 6.19/6.21

(``sumTok``, ``prodTok``, ``oplusTok``, ``otimesTok``) and the function spaces ``funSpace`` / ``strictFun``.

****Answer.**** The first five hold for all `?, ?`; the last fails in general.

relation	verdict	name
<code>`(???) ? (x ?)`</code>	**true**	<code>`otimes_trianglelefteq_prod`</code> (in fact <code>`otimesTok ? prodTok`</code>)
<code>`??? x ?`</code>	**true**	<code>`fst_trianglelefteq_prod`</code>
<code>`(???) ? (+ ?)`</code>	**true**	<code>`oplus_trianglelefteq_sum`</code> (in fact <code>`oplusTok ? sumTok`</code>)
<code>`??? ?`</code>	**true**	<code>`inl_trianglelefteq_oplus`</code>
<code>`(? -> False) ? (? -> ?)`</code>	**true**	<code>`strictFun_trianglelefteq_funSpace`</code>
<code>`??? ?`</code>	**false in general**	<code>`not_trianglelefteq_otimes_unit`</code>

The smash product collapses the bottom: pairing anything with ``False_?`` is ``False``. So ``?`` embeds in

``? ?`` only when ``?`` contributes a (finite) non-bottom point; for the trivial ``? = ?`` we have ``? ? ~ = ?``, refuting the universal claim.

All parts are ****choice-free**** (``#print axioms subseteq {propext, Quot.sound}``) except ``(4)`` (``inl_trianglelefteq_oplus``), whose ``oplus_mem_leftN`` decides the genuinely-undecidable test ``X = Delta_0`` over an arbitrary system and so depends on ``Classical.choice``.

/-! ## (4) `??? ?` -- left-injection projection pair

Unlike the product, the coalesced sum *identifies* the two bottoms, so the embedding of `?`
must
send `False ? = Delta_0` to the shared bottom `sumTokMaster` and a proper `X` to its left copy
`OX`. We
package this in `leftN X` (`= OX` for proper `X`, `= sumTokMaster` for `X = Delta_0`).

Distinguishing the two cases is exactly the test `X = Delta_0`, which is undecidable for an
arbitrary
neighbourhood; consequently the single lemma `oplus_mem_leftN` -- and only it -- uses `
Classical.em`.

This is genuinely unavoidable at this level of generality (Scott's tokens are concrete and
decidable,
but we work over arbitrary `NeighborhoodSystem`s), so `inl_triangleleftteq_oplus` depends on
`Classical.choice` (called out in the axiom audit). Every other part of Exercise 6.27 is choice
-free. -/

/-- The left-copy generator: `OX` for proper `X`, the shared bottom `sumTokMaster` for `X =
Delta_0`. The

/-! ## (5) `(? -> False ?) ? (? -> ?)` -- the strict maps embed in all maps

A strict map `*is*` an approximable map, so `? -> False ?` sits inside `? -> ?` by inclusion `
i`, with the
*strictification* `j` (force `f(False) = False`) as its retraction. `strictify f sqsub f`
always, and on a strict
`f` strictification is the identity; this gives the projection-pair laws `j comp i = id`,
`i comp j sqsub id`. We work over **arbitrary** systems `V_0, V_1` (not just `Str`); the
construction is
choice-free. We realise `i, j` on principal inputs via `ofMono` of the element-level inclusion
/
strictification, then identify their element maps using the representations `funSpaceEquiv`
(`|? -> ?| ? ApproximableMap`) and `strictFunEquiv` (`|? -> False?| ? StrictMap`). -/

# Exercise 6.28 (Scott 1981, PRG-19, S6) -- Plotkin's finite Cantor-Schroder-Bernstein

> **EXERCISE 6.28.** (Suggested by G. Plotkin). Show that if `?` and `?` are *finite* systems
and
> `? ? ? ? ?`, then `? ~=? ?`. Need the same be true of infinite systems?

Here `?` is Scott's *embeds-as-a-subdomain* relation of Lemma 6.15: `D ? E` means `D ~=? D'`
for
some subdomain `D' ? E`.

## The argument

The whole proof rests on a single observation: **`D ? E` already supplies an order embedding of
element domains `|D| ?o |E|` (`Triangleleftteq.elementEmbedding`). Indeed, unfolding `?` gives
an
order isomorphism `e : |D| ?o |D'|` onto a subdomain `D' ? E`, and Proposition 6.12 turns `D' ? E`
into a projection pair `i : D' -> E`, `j : E -> D'` with `j comp i = I`. The element-wise
map `i(*)` is
then an order embedding (`projElementEmbedding`): it is monotone (`toElementMap_mono`), and `j
(*)`
is a monotone left inverse, so `i(a) sqsub i(b) -> j(i(a)) sqsub j(i(b)) -> a sqsub b`
`. Compose with `e`.

For *finite* domains, mutual order embeddings force an isomorphism
(`orderIso_of_embeddings`): each embedding is injective, so the two finite element types have
equal
cardinality, whence either embedding is a bijection -- a surjective strictly-monotone map, i.e.
an
order isomorphism. This is the finite Cantor-Schroder-Bernstein, and it is exactly what Plotkin
's
hint exploits. (The retraction structure of `?` is *stronger* than a mere embedding, but the
proof
only needs the embedding.)

"Finite system" is read faithfully as *finitely many neighbourhoods*
(`NeighborhoodSystem.IsFinite`); this yields `Finite |D|` (`finite_element_of_isFinite`)
because a
filter is pinned down by which of the finitely many neighbourhoods it contains.

**Need the same be true of infinite systems? **No.** Plotkin's hint is the finite cardinality
count above; it has no infinite analogue. Mutual *retracts* of dcpos need not be isomorphic --
the
analogue of Cantor-Schroder-Bernstein fails for the retraction preorder once the domains are
infinite (a Eilenberg-swindle-style obstruction). Only the finite statement is formalized here;
the
infinite counterexample is recorded as prose, outside this file's scope.
```

```

Everything is **choice-free at the relational core** (`projElementEmbedding`,
`elementEmbedding` audit to `{proptext, Quot.sound}`); the finite count
(`orderIso_of_embeddings`, hence the main theorems) uses `Classical.choice` -- genuinely
unavoidable, as it extracts a `Fintype` from `Finite` and a surjection's section.

# Exercise 6.29 (Scott 1981, PRG-19, S6) -- infinitary sum and product

> **EXERCISE 6.29.** Generalize `+` and `x` to infinitary operations on domains:
> ` $\prod_{n=0}^{\infty} D_n$ ` and ` $\sum_{n=0}^{\infty} D_n$ `. Would a similar generalization be possible for
  ` $\prod$ ` and ` $\sum$ `?

We work with an arbitrary index type ` $\alpha$ ` and a family of neighbourhood systems `D : forall i,
  ?_i` over
token types ` $a_i$ ` (Scott's ` $D_n$ `, with ` $\text{Nat}$ ` the intended ` $\alpha$ `). Tokens of the combined systems
live in
`Sigma i, a_i` (for product-like operations) or `Option (Sigma i, a_i)` (for sum-like
operations, the
`none` being the fresh basepoint). This is the indexed analogue of the abstract binary
`prod`/`sum` over ` $a \ ? \ b$ ` / `Option (a ? b)`.

## The four operations and the answer

* ` $\prod_i D_i$ ` (`iprod`) -- the indexed product. A neighbourhood is a tuple ` $X_i$  in ` $?_i$ `
  that is
  the master in all but finitely many coordinates (a cylinder). The finite-support
  condition
  is essential: it is exactly what makes the compact elements of the product the finitely-
  presented
  ones, giving the headline result `iprodEquiv : |?_i D_i| ?o forall i, |D_i|` (the product
  order is
  pointwise) -- the infinitary Proposition 3.2.
* ` $\sum_i D_i$ ` (`isum`) -- the indexed separated sum. A neighbourhood is the basepoint
  master or
  a single tagged copy ` $\text{inj } i \ X$ ` of one summand (finite information -- only one coordinate is
  constrained), so no finite-support condition is needed. Element trichotomy `isum_trichotomy`:
  every element is `False` or lives in exactly one summand.
* ` $\coprod_i D_i$ ` (`ioplus`) -- the indexed coalesced sum, as ` $\sum$ ` but with the improper
  tagged
  copies deleted (the bottoms identified). Single-coordinate, so it generalizes fine.
* ` $\smashprod_i D_i$ ` (`iotimes`) -- the indexed smash product. A proper neighbourhood would need
  every
  coordinate proper (`!=` master), which over an infinite ` $\alpha$ ` contradicts finite support. So
  the
  infinite smash degenerates: `iotimes_only_master`/`iotimes_subsingleton` -- over an
  infinite
  index it has only the basepoint, a one-point domain.

Answer to Scott's question. ` $+$ `, ` $x$ `, ` $\prod$ ` all generalize to infinitary operations; ` $\sum$ `
  does
not -- the infinite smash collapses to the trivial domain.

Choice discipline. Every data construction is choice-free
(`iprod`, `isum`, `ioplus`, `iotimes`, the order iso `iprodEquiv`, and `isum_summand_unique`
all have
`#print axioms subseq {propeq, Quot.sound}`). The finite-support predicate is a `List` of
coordinates in
its positive form `forall i, i notin l -> X i = master`, which keeps intersection (`
  FinSupp.inter`) and the
reconstruction (`z_mem_of_slices`) constructive. Only two genuinely classical Prop-level
results
remain: `isum_trichotomy` (an excluded-middle case split on whether an element reaches a
summand) and
the degeneracy `iotimes_only_master`/`iotimes_subsingleton` (a cardinality argument through
Mathlib's
classical `Set.Finite`). Both are flagged in their docstrings.

# A choice-free recursion theory for Lecture VII (Scott 1981, PRG-19)

**Why this file exists -- we roll our own and reject mathlib's recursion theory here.**
Lecture VII ("Computability in effectively given domains") needs the notions *recursively
decidable* and *recursively enumerable*. mathlib *has* these (`Computable`, `ComputablePred`,
`REPred`, `Primrec`, `Partrec`), but in mathlib `v4.30.0` essentially every *correctness lemma*
of
that development is proved with tactics (`grind`, `lia`) or wrapper lemmas that *open
`Classical`* -- e.g. `Computable.const`, `Primrec.const`, `Nat.unpair_pair`, `Nat.sqrt_le`,
and
`Nat.Primrec.add`/`mul` all audit with `Classical.choice` in their axiom set. This project's
discipline is to keep *data* (and as much as possible) *choice-free* (`subteq` {propext,
Quot.sound}`),
so we deliberately decline mathlib's classical recursion theory and instead build the slice we
need
on the genuinely choice-free foundations: the raw inductives `Nat.Primrec` / `Nat.Partrec` (
whose
*constructors* are choice-free) and `Nat.sqrt` / `Nat.pair` / `Nat.unpair` (whose *definitions*
are
choice-free). The only tactic we lean on for arithmetic is `omega`, which is choice-free here
(unlike `grind`/`lia`).

The pattern: a relation on integer indices is *recursive* (decidable) when it has a
*primitive-recursive characteristic function* (`Nat.Primrec`, lifted to `Nat.Partrec` for the
recursive/`REPred` analogues). Tuples are encoded with `Nat.pair` (choice-free), and we reprove
the
pairing round-trips (`unpair_pair`, `pair_unpair`) choice-free here.

Everything in this file is `subteq` {propext, Quot.sound}`.

/! ## "Recursively decidable" predicates (Scott's notion, Definition 7.1)

A predicate is recursively decidable when it has a primitive-recursive  $\{0,1\}$ -valued
characteristic
function. Tuples are coded by  $\text{Nat.pair}$ . These are the building blocks Scott's Definition 7.1
needs
(relations on indices), and the closure lemmas ( $\text{of\_iff}$ ,  $\text{comp}$  = reindex,  $\text{and}$ ) let us
derive the
inclusion- and equality-deciders. All choice-free. -/

/-- A unary predicate  $p : \text{Nat} \rightarrow \text{Prop}$  is recursively decidable. -/
def RecDecidable (p : Nat → Prop) : Prop :=

/-! ## "Recursively enumerable" predicates (Scott's notion, Definition 7.2)

Scott's Definition 7.2 asks for the neighbourhood relation `X_n f Y?` to be *recursively
enumerable*. We model "recursively enumerable" choice-free as a **projection of a recursively
decidable relation**: `p` is r.e. iff there is a recursively decidable `q` with
`p n <=> exists i, q <i, n>` (the search variable `i` is paired with `n` via `Nat.pair`).

This is the
standard equivalent of Scott's prose description -- "there is a primitive recursive `r` with
`y = {Y_{r(i)} ? i in Nat}`": the projection form additionally represents the empty set (take
`q`
identically false), exactly as r.e. sets require. Every recursively decidable predicate is r.e.
(`RecDecidable.re`, dropping the search variable), and r.e.-ness transfers across pointwise
equivalence (`REPred.of_iff`). All choice-free. -/

/-- A unary predicate `p : Nat -> Prop` is **recursively enumerable**: it is the projection
of a
recursively decidable relation, `p n <=> exists i, q (Nat.pair i n)`. -/
def REPred (p : Nat -> Prop) : Prop :=
  exists q : Nat -> Prop, RecDecidable q /\ forall n, p n <=> exists i, q (Nat.pair i
    n)

/-- A binary relation is recursively enumerable when its `Nat.pair`-coding is. -/
def REPred_2 (r : Nat -> Nat -> Prop) : Prop :=
  REPred fun t => r t.unpair.1 t.unpair.2

/-- **Every recursively decidable predicate is recursively enumerable.** Use the decider as the
relation `q <i, n> := p n` (a reindex of `p` along `unpair.2`, dropping the search variable `i`
`); the
witness `i = 0` makes the projection trivial. -/
theorem RecDecidable.re {p : Nat -> Prop} (hp : RecDecidable p) : REPred p := by
  refine <fun t => p t.unpair.2, hp.comp Nat.Primrec.right, fun n => ?_>

/-! ### Closure properties of r.e. predicates (for Proposition 7.3 and Theorem 7.4)

The projection-of-decidable form makes r.e.-ness closed under primitive-recursive **reindexing
**
(`REPred.comp`), **conjunction** (`REPred.and`, pairing the two search variables), and
**existential projection** over `Nat` (`REPred.proj`, absorbing the projected variable into the
search
variable). These are exactly the moves Scott's `g comp f` needs: `X (g comp f) Z <-> exists
Y, X f Y /\ Y g Z`. -/

/-- **Reindexing.** If `p` is r.e. and `g` is primitive recursive, then `fun n => p (g n)` is r
.e.
(absorb `g` into the decidable relation along `unpair.2`). -/

/-! ## A choice-free primitive-recursive fold engine over `Nat`-coded lists

Scott's function-space deciders (Theorem 7.5) range over *finite lists* of neighborhood indices
.
To stay choice-free we encode such a list as a single natural via `encodeList` and process it
with a
genuinely primitive-recursive `foldCode`. The key results are:

* `encodeList`          -- `List Nat -> Nat`, with `l.length <= encodeList l` (`
  encodeList_length_le`);
* `foldCode stp p z c`  -- folds the list coded by `c`, threading an accumulator and a fixed
  parameter `p`, with `stp` the (coded) step function;
* `foldCode_eq`         -- `foldCode` on `encodeList l` equals the corresponding `List.foldl
  `;
* `primrec_foldCode`    -- `foldCode` is primitive recursive in all of its (primrec) inputs.

`foldStep` walks one entry: the state is `pair remainingCode accumulator`; an empty remaining

```

```

code
(`= 0`) is a fixed point, otherwise it pops the head and applies `stp`. -/

/-- `b <= pair a b` (choice-free; avoids mathlib's `Nat.right_le_pair` to keep the axiom set

/-! ## Halving (`/2`, `%2`) for per-subset bit extraction

The funSpace consistency fold walks a step-list while consuming a subset bitmask `b` one bit at
a
time: at each entry it reads `b % 2` (is this entry in the subset?) and recurses on `b / 2`.
Only
division/modulus by the literal `2` is needed -- which `omega` discharges directly -- so this
stays
choice-free without a general `div`/`mod`. Computed jointly by `halfParity n = pair (n/2) (n%2)`.
` . -/

/-- `halfParity n = pair (n / 2) (n % 2)`, built by structural recursion: from `(h, p)` for `n`
`, the

/-! ## Bounded universal quantification of an r.e. predicate over a coded list

The "computable elements = computable maps" half of Theorem 7.5 needs r.e.-ness closed under
`forall e in decodeList c, p e` for an r.e. `p`. Classically this is the standard "bounded
forall ` of r.e. is
r.e."; choice-free we realise the search for the finite tuple of witnesses as a *single* code `
w`
whose decoded list supplies one witness per list entry, threaded through a `foldCode`. -/

/-- The pure (set-theoretic) witness-threading fold step. The accumulator is `pair remWitness
  flag` :
at the list head `x` we pop a witness `i` (the `decodeList` head of `remWitness`, i.e.
`(remWitness - 1).unpair.1`) with new remaining code `(remWitness - 1).unpair.2`, and `AND` the
  flag
with `isOne (qc <i, x>)`. -/
def reForallF (qc : Nat -> Nat) (acc x : Nat) : Nat :=
  Nat.pair (acc.unpair.1 - 1).unpair.2
    (selectFn acc.unpair.2 (isOne (qc (Nat.pair (acc.unpair.1 - 1).unpair.1 x)))) 0)

/-- The `foldCode`-form step (parameter unused), used to package `reForallF` primitive-
  recursively. -/
def reForallStp (qc : Nat -> Nat) (w : Nat) : Nat :=

/-! ### Bounded `forall` over a coded list with a parameter (for `curry`, Theorem 7.5)

```

```

`curry`'s neighbourhood relation is a bounded `forall e in decodeList c, p n e` whose body
depends on a
*parameter* `n` (the `?_0`-index) as well as the list entry `e`. We reduce this to
`REPred.forall_mem_decodeList` by primitively-recursively re-coding the list `decodeList c`
into the
list of pairs `` (order is irrelevant under `forall in`), so the parameterised body
becomes the
plain `fun s => p s.1 s.2` over the re-coded list. -/

/-- Prepend the *pair* `` onto the list coded by `acc`. -/
def mapPairStep (n acc x : Nat) : Nat := Nat.pair (Nat.pair n x) acc + 1

/-- `foldCode`-shaped wrapper of `mapPairStep` (parameter `n` threaded via the `params` slot).

/-! ## Choice-free primitive-recursive bitwise OR (for Example 7.8, the powerset `PN`)

Scott's Example 7.8 enumerates the finite subsets of `Nat` by `E_n = {k ? n.testBit k}` and
presents the
powerset domain `PN` with neighbourhoods `Nat ? E_n`. The intersection of two neighbourhoods is
`(Nat ? E_n) ∩ (Nat ? E?) = Nat ? (E_n ∪ E?) = Nat ? E_{n ||| m}` (bitwise OR), and Scott
notes that the
relation `E_n ∪ E? = E_k` is *recursive*. The presentation therefore needs `(n, m) |-> n
||| m` as a
**primitive-recursive** intersection function.

mathlib's `Nat.lor` is defined through `Nat.bitwise`/`binaryRec`, none of which is exposed as a
`Nat.Primrec`. We build it choice-free by *iterating* a fixed step `lorStep` (which strips the
low
bit of each argument, ORs them, and accumulates with a doubling weight). The result coincides
with
`Nat.lor` (`myLor_eq_lor`), so all the set-level facts can use mathlib's clean `Nat.testBit_lor`
`. -/

/-! ## Bounded quantifiers over a coded list preserving recursive *decidability*

`reForallChar`/`REPred.forall_mem_decodeList` above handle bounded `forall` over `decodeList`
for *r.e.*
predicates (which need a witness search). When the body is already recursively *decidable* the
story
is simpler: fold the `{0,1}` decider over the list with a Boolean `AND` (for `forall`) or `OR`
(for `exists`),
no witness threading. These are exactly what Scott's Smyth power-domain equality relation
(Proposition 7.10) needs: equality of two finite unions of down-sets unfolds to
`(forall a in A, exists b in B, ...) /\ (forall b in B, exists a in A, ...)` , a
nested bounded forall /exists over coded lists. All
choice-free. The list is coded by the *first* argument; the *second* argument is a free
parameter
threaded through the `foldCode` `params` slot. -/

/-- AND-fold step (`foldCode` shape): `acc |-> acc /\ isOne (g <head, params>)` -/

/-! ## Course-of-values fuel recursion -> joint primitive recursiveness

`decodeFuelOkChar`, `matchesBChar`, `autStateCardFuelChar` are each defined by structural
recursion on a `fuel : Nat` parameter, where the recursive step (`decodeFuelOkCharBody`, etc.)
applies the *previous* fuel level's function `prev : Nat -> Nat` at sub-codes of its own
input `c`
(via `Nat.unpair`), not merely at `c` decremented. Each is only known `Nat.Primrec` *for a
fixed
external `fuel`* (`forall fuel, Nat.Primrec (fun c => F fuel c)`) -- that is not enough once `
fuel`
itself must vary with the input (as it does for `ssysActiveChar`, C9b7, where `fuel := n.unpair
.2
+ 1`). Getting a genuinely joint `Nat.Primrec (fun t => F t.unpair.1 t.unpair.2)` needs
course-of-values recursion: tabulate `F fuel` at every code up to a bound as a coded list
(`tabCode`/`nthCode`), and iterate that *table transform* via `Nat.rec` on `fuel`, mirroring
`tabCode`'s own already-established proof pattern. Since `Body`'s sub-queries at code `c` are
always `<= c` (chains of `Nat.unpair` projections), a table covering `[0, c]` is self-
sufficient
throughout the whole recursion -- no growing/re-tabulating needed as fuel increases. -/

/-- One fuel-recursion step, applied to every code in `[0, bound]` at once. `bodyLookup`
represents `Body`'s step with `prev` replaced by table lookup: semantically `bodyLookup (pair
table c) = Body (fun c' => nthCode table c' 0) c` (see `fuelTable_eq_of_recursion`). -/
def fuelTableStep (bodyLookup : Nat -> Nat) (bound prevTable : Nat) : Nat :=
  tabCode (fun w => bodyLookup (Nat.pair w.unpair.2 w.unpair.1))
  (Nat.pair (bound + 1) prevTable) (bound + 1)

theorem fuelTableStep_nth {bodyLookup : Nat -> Nat} {bound prevTable i : Nat} (hi : i <=
  bound) (d : Nat) :
  nthCode (fuelTableStep bodyLookup bound prevTable) i d = bodyLookup (Nat.pair prevTable i)
  := by
  unfold fuelTableStep
  rw [tabCode_nth_lt (show i < bound + 1 by omega)]
  simp only [unpair_pair_fst, unpair_pair_snd]

/-- Tabulates the fuel-recursive function with base value `0` and step `bodyLookup` at every
code
in `[0, bound]`, as a coded list, for `fuel` iterations. -/
def fuelTable (bodyLookup : Nat -> Nat) (bound fuel : Nat) : Nat :=

/-! ## Exercise 7.22 C9b5 -- `autStateCardFuelChar`, `matchesBChar`

Fuel-bounded numeric mirrors of `autStateCard` / `matchesB` with tag dispatch like
`decodeFuelOkCharBody`. Godel coding matches `SEExpr.encode` in `Exercise722Presentation.lean`
(tags `0..3`, payloads at `c.unpair.2` / nested pairs). -/

open Scott1980.Neighborhood Exercise722

/-- **Not** `private`: `Exercise722Presentation.lean` (downstream of this file via `
  Definition71`)
bridges this to its own `boolNat` in Session **C9b7**, since `Recursive.lean` cannot import
`Exercise722Presentation.lean` (would cycle) and so cannot state that bridge itself. -/
def c9b5_boolNat (b : Bool) : Nat := if b then 1 else 0

/--! ### `matchesBChar` jointly primitive recursive in `(fuel, code)`, `code := pair c cw`

Harder than `decodeFuel0kChar`/`autStateCardFuelChar`: the cat branch's recursive calls are at
`pair a.unpair.2.unpair.1 (takeCode i cw)` / `pair a.unpair.2.unpair.2 (dropCode i cw)` -- the
word
half is a *derived* code (`takeCode`/`dropCode`), not a plain `Nat.unpair` projection, so
`hlocal` additionally needs `takeCode_le`/`dropCode_le` (proved above) alongside `pair_le_pair`
`. -/

/-! ## Exercise 7.22k (Session C7b, optional) -- `subsetBChar`, `interEqChar`

`Exercise722Equiv.lean` builds a *Bool-level* decider `interEqB` for language equivalence
(`denote e_1 = denote e_2`), via a choice-free `Finset`-valued subset-construction simulation
of
`toNFA e` (needed since `.cat` makes `toNFA e` genuinely nondeterministic -- "e_2 rejects w" is
a
universal statement over nondeterministic paths, which doesn't pump the way existential
acceptance does). That construction is cited here only for its length bound
(`exists_diff_word_short`, wrapped in `subsetB_iff`/`interEqB_iff`); the numeric mirror below
does
not re-encode `Finset (autState e)` at all -- `interEqB`'s own definition is just a bounded
search calling `matchesB`, which already has a joint `(fuel, code)`-primitive-recursive mirror
(`matchesBChar`, C9b5/C9b8). Only the bound formula and the bounded-forall wiring are new.
-/-

```

```

/-- Numeric mirror of `Fintype.card (Finset (autState e_1) x Finset (autState e_2))`
(`exists_diff_word_short`'s state-count bound), via `autStateCard_eq_card` +
`Fintype.card_finset`/'`card_prod`. -/
def subsetBoundChar (fuel c1 c2 : Nat) : Nat :=
  2 ^ (autStateCardFuelChar fuel c1) * 2 ^ (autStateCardFuelChar fuel c2)

/-- `{0,1}` gate: code `i` is a valid bit-string of length `<= subsetBoundChar fuel c1 c2`.
Screens
out both non-bit-string codes (`allBinDigitsChar`) and over-long ones (`listLenChar` vs the
bound),
so the bounded-forall search below never needs the (false) converse of `codeBound_ge`. -/

# Definition 7.1 (Scott 1981, PRG-19, S7) -- computable presentations / effectively given
domains

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII,
*Computability in effectively given domains*.

Scott's idea: the *finite elements* of  $\omega^\omega$  are the ones initially known, and to know a finite
element is to know how it is **related** to the other finite elements. As finite elements are
in
one-one correspondence with neighbourhoods (Definition 1.7), the data reduces to *recursive
calculations with neighbourhoods*. This forces at most a countable infinity of neighbourhoods.

> **Definition 7.1.** A neighbourhood system  $\omega^\omega$  has a *computable presentation* provided we
can
> write  $\omega^\omega = \{X_n \mid n \in \mathbb{N}\}$ , where the two relations
>

```

```

> * (i)  $\exists X_n \text{ I } X? = X_k$ , and
> * (ii)  $\exists k. X_k \subseteq X_n \text{ and } X_k \subseteq X?$ 
>
> are recursively decidable (in  $n, m, k$  and in  $n, m$  respectively).

**Recursion theory: we roll our own and reject Mathlib here.** "Recursively decidable" is
modelled by
`Domain.Recursive.RecDecidable` -- the existence of a primitive-recursive  $\{0,1\}$ -valued
characteristic function, with tuples coded by `Nat.pair`. We deliberately do not use
Mathlib's
recursion theory (`ComputablePred` / `Primrec` / `Partrec`): in Mathlib `v4.30.0` essentially
all of
its *correctness lemmas* are proved with `grind`/`lia` or the  $\text{@[simp]}$  lemma `Nat.unpair_pair`
,
which open `Classical`**, so they audit with `Classical.choice`. This project's discipline is
to
keep constructions choice-free ( $\subseteq$  {propext, Quot.sound}), so we rebuilt the slice of
recursion
theory we need (choice-free `Nat.sqrt` correctness, the `Nat.pair`/`unpair` round-trips, and
primitive-recursive  $\text{id}/+/*$ ) in `Domain/Neighborhood/Recursive.lean`. Relation (i) is the
ternary  $\text{interEq}$  predicate (`RecDecidable_3`); relation (ii) is the binary consistency
predicate
(`RecDecidable_2`). The enumeration  $X$  is the only *data* the structure carries (a plain
`Nat → Set a`), so building a presentation stays choice-free.

The intuitive content (Scott's prose): (i) lets us *locate* the intersection of two
neighbourhoods
in the standard list, and (ii) is the *consistency condition* -- the necessary and sufficient
condition for the intersection to exist in  $?$ . Scott immediately remarks the biconditional
 $X_n \subseteq X? \iff X_n \text{ I } X? = X_n$ , which makes the inclusion relation decidable
from (i); we record this
as `ComputablePresentation.incl_computable`, and equality of neighbourhoods as `eq_computable`.

A neighbourhood system is *effectively given* when it admits such a presentation
(`NeighborhoodSystem.IsEffectivelyGiven`). The one-point system  $?$  is the sanity inhabitant
(`unitSys_isEffectivelyGiven`).

# Definition 7.2 (Scott 1981, PRG-19, S7) -- computable maps and computable elements

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII,
*Computability in effectively given domains*.

> **Definition 7.2.** Given two recursively presented domains `? = {X_n ? n in Nat}` and
> `? = {Y? ? m in Nat}`, an approximable mapping `f : ? -> ?` is said to be *computable*
iff the
> relation `X_n f Y?` is **recursively enumerable** in `n` and `m`.

Why r.e. (and not recursive)? Scott answers by degenerating `?` to the one-point domain `{Delta}`: then
`f` is just a single element `y = f({Delta})` in `|?|`, and the condition reduces to the index
set
`{m ? Y? in y}` being r.e. A *finite* element has a recursive index set, but an infinite
element can
only be approximated "a little at a time" -- its approximations can be *listed* (r.e.) but
membership
need not be decidable. So 7.2 already incorporates the notion of a **computable element**
(`IsComputableElement`).

We model `IsComputableMap` as `REPred_2 (fun n m |>-> X_n f Y?)` over the choice-free
recursion theory of

```

`Recursive.lean` (`REPred` = projection of a recursively decidable relation; see that file for why we roll our own and reject Mathlib's classical recursion theory).

****Proposition 7.3**** is then formalized in full:

```
* `idMap_isComputable` -- the identity map is computable, because `X_n I X? <-> X_n subseq
X?`
(`ComputablePresentation.incl_computable`) is recursively *decidable*, hence r.e.
* `comp_isComputable` -- the composition of computable maps is computable: `X_n (g comp f) Z?`
is
`exists Y?, X_n f Y? /\ Y? g Z?` (surjectivity of the middle presentation lets `Y` range
over indices
`1`), which is r.e. by the closure lemmas `REPred.comp`/`REPred.and`/`REPred.proj`.
* `apply_isComputableElement` -- Scott's stated consequence: a computable map applied to a
computable
element gives a computable element (`f(x) = {Y? ? exists X_n in x, X_n f Y?}`, again r.e.
by the closure
lemmas).
```

Two further faithful facts:

```
* `principal_isComputableElement` -- every **finite** (principal) element `X_n` is computable,
since
its index set `{m ? X_n subseq X?}` is a recursive slice of `incl_computable` (Scott's
remark that
finite elements have recursive index sets).
```

Everything here is `subseq {propxt, Quot.sound}` (choice-free): it is built only from the choice-free deciders of Definition 7.1 and the choice-free r.e. layer of `Recursive.lean`.

# Theorem 7.4 (Scott 1981, PRG-19, S7) -- `+` and `x` preserve effective givenness

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Theorem 7.4.** If `?_0` and `?_1` are effectively given, then so are `(?_0 + ?_1)` and `(?_0 x ?_1)`.
> Moreover the combinators `in_i`, `out_i`, `proj_i` are all computable; further, if `f` and `g` are
> computable maps, then so are `f + g` and `f x g`.

**This file: the product `(x)` half.** Scott takes `?_0 x ?_1 = {X_n? U X?1 ? n, m}` with
a one-one
pairing function `r(n, m)` and `W_k = X?_{p(k)} U X1_{q(k)}`; we realize `r = Nat.pair`,
`p = *.unpair.1`, `q = *.unpair.2`, and the project's `prodNbhd`/`prod` (over `a ? b`,
`Product.lean`). The product is *uniform* (no tag analysis), so both of Scott's relations
decompose
into **conjunctions** of the components' relations under index reindexing, handled entirely by
the
choice-free closure layer of `Recursive.lean` (`RecDecidable.and`/`.comp`/`.of_iff`):

* `prodPresentation`, `prod_isEffectivelyGiven` -- the product is effectively given;
* `proj_0_isComputable`, `proj_1_isComputable` -- `(X_n? U X?1) proj_i Z <-> (component)
  subseteq Z` is recursively
*decidable* (a slice of `incl_computable`), hence r.e.;
* `paired_isComputable` -- `` is computable when `f, g` are (conjunction of two r.e.
  relations);
* `prodMap_isComputable` -- `f x g` is computable, via `f x g = <f comp p_0, g comp p_1
  >` (Exercise 3.19) and
  `comp_isComputable` (Proposition 7.3).

The sum `(+)` half -- which needs tag analysis, hence a little more choice-free recursion
theory

```

```

(truncated subtraction, equality/disjunction deciders) -- is in the companion development.

Everything here is `subseteq {propeq, Quot.sound}` (choice-free).

/-! ## The sum (+) half of Theorem 7.4

The sum ` $?_0 + ?_1$ ` (`Exercise318.lean`, over `Option (a ? b)`) has *three* kinds of
  neighbourhood --
the master ` $\{?\} U 0\Delta_0 U 1\Delta_1$ `, the left copies `0X`, the right copies `1Y` -- so its
  presentation deciders
require a genuine tag analysis (Scott: "the neighbourhood relations have to be worked out in

```

```

    terms of
the indices ... recursively enumerable relations ... closure under conjunctions, disjunctions,
..."). We
enumerate with a `Nat.pair` tag: `tag 0 |-> 0X??`, `tag 1 |-> 1X1?`, `tag >= 2 |-> `
master. -/

/-- Choice-free three-way split of a tag `n` in  $\{0, 1, \geq 2\}$  (via `Nat.decEq`, not classical
`em`). -/

# Theorem 7.5 (Scott 1981, PRG-19, S7) -- `(?_0 -> ?_1)` is effectively given

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Theorem 7.5.** If `(?_0)` and `(?_1)` are effectively given, then so is `(?_0 -> ?_1)`. The
  combinators
> `eval` and `curry` are computable, provided all the domains involved are effectively given.
  The
> computable elements `f` in `|?_0 -> ?_1|` are exactly the computable maps `f : ?_0 -> ?_1`
  `.

This file builds the theorem in green, audited, **choice-free** milestones (see `HANDOFF.md`).

## Milestone 1 -- Proposition 3.9(i), the consistency condition (forward, choice-free)

The keystone is Scott's 3.9(i): a function-space neighbourhood `[X_i, Y_i]` is non-empty iff
for every
subset `I` of indices with `{X_i ? i in I}` consistent in `(?_0)`, the outputs `{Y_i ? i in I}`
are consistent
in `(?_1)`. We model a subset by a **sublist** `sub sqsub L` (this is what the eventual
primitive-recursive
decider enumerates, one entry/bit at a time), and the intersection of a finite list of
neighbourhoods

```

by `interList`. The forward direction -- non-empty ? the subset condition -- is choice-free:
 given a
 witness map `f` in `stepFun L` and a common lower neighbourhood `Z` of the selected inputs, `f`
 relates
`Z` to the intersection of the selected outputs (a finite `inter_right` fold over the `*explicit`
`*`
 selection, so `**no undecidable X subseq X_i` case-split is needed**), whence that
 intersection is a
 neighbourhood by `f.rel_cod`.

(The reverse direction is genuinely decidable only relative to the presentations -- it needs
`?_0`-inclusion to be decidable to single out `{i ? X subseq X_i}` -- and is developed with
 the decider.)

/-! ### Milestone 2 -- the consistency characterization over coded entry-lists.

A function-space neighbourhood is presented by a list `el : List Nat` of *entry codes*: each `e`
in `el`
codes a step pair `[X_{e.1}, Y_{e.2}]` via `Nat.pair`. `funListOf` turns `el` into the list of
step
pairs, and `stepFun (funListOf el)` is the neighbourhood `[X_{e_i.1}, Y_{e_i.2}]`.

The characterization `stepFun_funListOf_nonempty_iff` is Scott's 3.9(i): the neighbourhood is
non-empty iff for every *sub-selection* `sub sqsub el` whose inputs have a common lower
neighbourhood
`Z` in `?_0`, the intersection of the selected outputs is a neighbourhood of `?_1`. The reverse
direction
builds the least map `leastMap`; its consistency hypothesis is discharged input-by-input by
**filtering `el` with the (choice-free) decidable `?_0`-inclusion test** supplied by the
presentation
`P_0`, so it stays `subseq {propxt, Quot.sound}`. -/

/-! ### Milestone 3a -- deciding consistency of a finite index set via the `inter`-chain.

To decide whether a finite list of neighbourhood indices `js` is *consistent* in `?` (i.e.
whether
`{X_j ? j in js}` is a neighbourhood) we fold the presentation's primitive-recursive `inter`
along
`js`, starting from `masterIdx`, to obtain an index `idxchain js`. The crisp characterization
is:

> `js` is consistent **iff** `X_{idxchain js} subseteq X_j` for every `j in js`.

The point is that `X_{idxchain js}` is *always* a neighbourhood (`mem_X`), so if it sits inside
every
`X_j` it witnesses consistency; conversely, when consistent, `inter`'s spec (and the fact that
a
subset of a consistent set is consistent) makes the chain compute the genuine intersection.
This
replaces any consistency-flag bookkeeping by a single `inter`-fold plus a bounded inclusion
check --
all choice-free. -/

/#!/ ### Milestone 3b -- bitmask sublist selection.

The eventual decider enumerates the *subsets* of an entry-list one **bit** at a time: `
  bitSelect L b`
keeps the entries of `L` whose position is set in the binary expansion of `b` (low bit = head).
  Every
sublist arises as some `bitSelect L b` with  $b < 2^{\text{L.length}}$  (`exists_bitSelect_lt`), so a
universal statement over sublists is a *bounded* universal statement over bitmasks
(`forall_sublist_iff_forall_bitmask`) -- and bounded-`forall` of a recursively decidable
predicate is
recursively decidable (`RecDecidable.bForall`). All choice-free. -/

/-! ### Milestone 3c -- the single-pass consistency fold (`section ConsFold`, generic over `P`)
.

To decide whether a *bitmask-selected* sublist of an index list is consistent, we fold once
over the
list threading a state `s = pair b (pair idx flag)`: `b` the remaining bitmask, `idx` an index
of the
running intersection `{X_j | j selected so far}`, and `flag` in `{0,1}` recording whether **
every
prefix has been consistent**. At a selected entry we set `idx := P.inter idx (projFn x)` and
`flag := flag /\ [P.cons_computable says X_idx I X_{projFn x} is consistent]`. The headline
`consUpd_foldl_spec` shows the final flag is `1` iff the selected intersection is a
neighbourhood
(using `inter_spec` to keep `X_idx` exact along the consistent prefix, and the fact that the *
full*
intersection being a neighbourhood forces every prefix to be one). All choice-free. -/

section ConsFold

variable {V : NeighborhoodSystem α} (P : ComputablePresentation V)

/-! ### Milestone 3d -- assembling the function-space consistency decider `funCons_decidable`.

`stepFun_funListOf_nonempty_iff` (Milestone 2) characterises non-emptiness as a universal
statement
over sublists; `forall_sublist_iff_forall_bitmask` turns it into a *bounded* universal over
bitmasks

```

```

`b < 2^c`; `antecedent_cons_iff` / `funConsequent_eq` rewrite the per-bitmask antecedent and
consequent into the `interFrom` form decided by `consFold_decidable`. The implication of two
recursively decidable predicates is recursively decidable (`not`/`.or`/`.em`, choice-free),
and a
bounded universal of a recursively decidable predicate is recursively decidable
(`RecDecidable.bForall`). -/

/-! ### Milestone 5b -- the function-space inclusion / equality / consistency deciders.

We now turn the choice-free characterization of Milestone 5a into recursive deciders for the function-space presentation. Two small generic facts first; then the `interYs`-index fold (a *conditional* `inter`-chain over `?\_1`, gated by the decidable `?\_0`-inclusion test); then the deciders themselves. All choice-free. -/

```

/-- `selectFn` driven by `isOne` is a `Nat`-equality `if` (choice-free; `decEq` on `Nat`). -/

```

/-! #### The `interYs`-index fold: a conditional `inter`-chain over `?\_1`.

For a presented list `funListOf (decodeList a)` and a `?\_0`-index `k`, the set `interYs Delta\_1 (funListOf (decodeList a)) (X\_0\_k)` is the intersection of the outputs `X\_1\_{e.2}` over the

Lean 4 source (lines 801–1200)

entries `e` of `decodeList a` whose input dominates `X\_0\_k` (`X\_0\_k subseq X\_0\_{e.1}`). We compute an index of it by folding `P\_1.inter` over `decodeList a`, intersecting at an entry exactly when the (decidable)

inclusion test fires. `condSet k A el` is the running set; `interYsFoldl\_spec` is the index correctness (when the result is consistent), mirroring `interFrom\_eq\_of\_foldl`. -/

/-- The running set of the conditional `inter`-chain: `A` intersected with the outputs `X_1_{e

/--! #### A concrete `{0,1}` characteristic function for function-space consistency.

`funCons_decidable` already shows consistency is recursively decidable, but to use it in *data*
(the
function-space enumeration branches on it) we need a *concrete* primitive-recursive char rather
than
one extracted from an existential (extraction needs choice). We build it explicitly from the
component presentations' consistency chars `fc0`/`fc1`, and prove its spec via `funCons_iff`.

/-! ### Milestone 8 -- computable elements of `(?_0 -> ?_1)` are exactly the computable maps.

Scott (Theorem 7.5): *"The computable elements `f` in `|?_0 -> ?_1|` are exactly the
computable maps
`f : ?_0 -> ?_1`."* Under the completeness isomorphism `toApproxMap` (Theorem 3.10), a filter
`phi` of the
function space corresponds to the approximable map `f-hat = toApproxMap phi`, and `phi.mem [X,
Y] <-> X f-hat Y`.
The enumeration `Xenum c` of a *consistent* code is the finite intersection `?[X_0_{e_i}, X_1_{e_i}]`, so
`phi ? Xenum c <-> forall e_i, phi ? [X_0_{e_i}, X_1_{e_i}]` (the generation lemma `
mem_stepFun_iff`); junk codes map
to `univ`, always in `phi`. Hence the element index set `{c ? Xenum c in phi}` is r.e. iff
the single-step
relation `{<n,m> ? [X_0_n, X_1_m] in phi}` is -- the map's neighbourhood relation. The map ?
element half is
the choice-free *bounded-`forall` over a coded list* closure `REPred.forall_mem_decodeList`.

/-! ### Milestone 7 -- `eval` is computable.

Scott (Theorem 7.5): "The combinators `eval` and `curry` are computable, provided all the
domains

```

involved are effectively given."* The evaluation map ``eval : (?_0 -> ?_1) x ?_0 -> ?_1`` sends ``(F, X)`` to ``Y`` iff **every** map ``f`` in ``F`` relates ``X`` to ``Y`` (Theorem 3.11), i.e. ``F`` `subseq` `[X, Y]` (the step neighbourhood, viewed as the set of maps relating ``X`` to ``Y``). On the product presentation ``prodPresentation funPresentation P_0``, the neighbourhood at index ``k`` is ``Xenum_{k.1} x X_0_{k.2}``, so

$$(Xenum\ c, X_0?)\ eval\ Y_1? \iff Xenum\ c\ subseq\ [X_0?, Y_1?].$$

The single step ``[X_0?, Y_1?]` is itself a one-entry function-space neighbourhood -- ``Xenum`` of the (always consistent) code ``<<j, m>, 0> + 1`` -- so the relation is exactly the **decidable** function-space inclusion ``funPresentation.incl_computable``, re-indexed by a primitive-recursive code map. This is Scott's observation that ``eval`` is a **recursive** set; r.e.-ness (hence computability) and choice-freeness follow. -/

```

/-- **The step neighbourhood `[X_0?, Y_1?]' as a one-entry `Xenum`.** The code `<<j, m>, 0> + 1`
decodes to the singleton entry-list `<<j, m>`', which is always consistent (the step map itself
is a
witness), so `Xenum` of it is `stepFun [(X_0?, Y_1?)] = [X_0?, Y_1?]'`. -/

# Theorem 7.6 (Scott 1981, PRG-19, S7) -- `fix : (? -> ?) -> ?` is computable

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Theorem 7.6.** For any effectively given domain `?`, the combinator `fix : (? -> ?) ->
?` is
> computable.

Scott's proof reads off the neighbourhood relation of `fix` from the fixed-point construction
of
Theorem 4.1/4.2: writing `? = {X_n}` effectively given,

`?_{i<q} [X_{n_i}, X_{m_i}] fix X_?` iff for some finite sequence `Delta = X_{k_0}, ..., X_{k_p} = X_?`
we have, for each `j < p`, `{ X_{m_i} ? X_{k_j} } subseteq X_{n_i} } subseteq X_{k_{j+1}}`.

Inside "for some finite sequence" all the checks are *decidable* (by the effective presentation
), and
the existential quantification of a decidable predicate is recursively enumerable. (Since there
is no
bound on the length of the sequence, this is genuinely r.e. and not generally recursive.)

## Strategy (choice-free)

```

```

The function-space neighbourhood `F = Xenum c` (Theorem 7.5) is a finite intersection
`?[X_{n_i}, X_{m_i}]`; its *least map* is `g = toApproxMap (F)`, and `(fix V).rel F (X_?)`
unfolds via
`rel_iff_mem_principal` + `fixMap_toElementMap` + `mem_fixElement` to

`exists p, (g?).rel Delta (X_?)`.

The one-step relation `g.rel (X_a) (X_b) <-> F subseq [X_a, X_b]` is exactly Scott's
`?[X_{m_i} ? X_a subseq X_{n_i}] subseq X_b`, and -- crucially -- it is **recursively
decidable**, because
`[X_a, X_b] = Xenum (codePair a b)` (a one-entry, always-consistent function-space
neighbourhood) so
the test is the decidable function-space inclusion `Xenum c subseq Xenum (codePair a b)`
(`funPresentation.incl_computable`, Theorem 7.5).

We model a finite `g`-chain by a **list of indices** (using `surj` to name each intermediate
neighbourhood) and prove the characterisation `(fix V).rel (Xenum c) (X_?) <-> exists full,
gStepsOK ...`
(soundness/completeness over the list, choice-free). The existential over the list is then
realised
as the r.e. `exists i, q (pair i n)`, where `q` decodes `i` to the chain, runs a single
primitive-recursive
`foldCode` (`fixChainChar`) threading the previous index and a `{0,1}` consistency flag, and
checks
the flag together with the final inclusion `X_{last} subseq X_?`. Everything audits
`subseq {propeq, Quot.sound}`.

# Proposition 7.7 (Scott 1981, PRG-19, S7) -- `D^S` is effectively given

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> Proposition 7.7. For any effectively given domain `D`, the domain `D^S` is also
  effectively
> given, and all the combinators of Example 6.1 prove to be computable.

Scott transposes everything back to `Nat` and gives the enumeration of `D^S` (Example 6.1's
tree
algebra, `Example61.Dsharp`) by a course-of-values recursion. In our model `D^S` lives over
`List Bool x a` (Example 6.1), so the enumeration is `V : Nat -> Set (List Bool x a)`:

* `V 0 = Gamma` (the master neighbourhood of `D^S`);
* `V (2n+1) = 0*X_n` (`embZero` of the `n`-th `D`-neighbourhood `X_n = P.X n`);
* `V (2n+2) = 1*V_{p n} U 2*V_{q n}` (`embPair` of two earlier neighbourhoods).

Here `p n = n.unpair.1` and `q n = n.unpair.2` are Scott's `p, q` (inverse pairing): both are
<= n`,
hence the subscripts `p n, q n` of `V_{2n+2}` are `< 2n+2`, so the recursion is well-founded
and
membership stays recursive -- exactly Scott's observation.

This file builds the construction in milestones:

* Foundational layer (this commit): Vsharp and its core math -- mem_X (each `V k` in
  ?^S),

```

```

`surj` (every `?^S`-neighbourhood is some `V k`), nonemptiness. All choice-free.

/-! ### `MemS`-subset inversions and the consistency-via-subset equivalences.

A nonempty `D^S`-neighbourhood contained in `embZero Y` must itself be an `embZero` (its tokens
have
empty `{1,2}`-path); contained in `embPair A B`, an `embPair`. These give the bridge between
Scott's
consistency relation on `D^S` (`exists l, V_l subseteq V_n I V_m`) and the recursive sub-
checks: `embZero`
consistency reduces to `D`'s, and `embPair` consistency to the two components'. -/

/#!/ ### A primitive-recursive course-of-values memo evaluator.

The `D`S` deciders (`cons`, `inter`, equality) recurse on the index *trees*: e.g.
`inter(2a+2, 2b+2)` recurses on `inter(a.1, b.1)` and `inter(a.2, b.2)`. The combined measure
`w = Nat.pair n m` strictly decreases on every recursive call, so each decider is a **unary
course-of-values recursion** on `w`. We realise course-of-values by a primitive-recursive *memo
table*: `rtbl step w` codes the reverse list `[g(w-1), ..., g 0]` (`g v = step (pair v (table
  for v))`),
built by a single `Nat.Primrec.prec` whose step is a cons. To read `g v` for `v < w` inside `
step`,
we look up position `w-1-v` of the reverse table via `listGet`. All choice-free. -/

/-- One step of the list-indexing fold: state `pair countdown value`; capture the current
  element
when `countdown = 1`, else carry the value and decrement. -/

/-! ### The combined `D`S` decider step (`eq`/`cons`/`inter` triple).

All three `D`S` deciders recurse the same way on `(i, j)`, so we compute them together as a
packed
triple `packT eqBit consBit interIdx`. The step `dsharpStep fcons feq finter` is fed Scott's
three
`D`-level primitive-recursive functions: `fcons`/`feq` are the extracted `{0,1}` characteristic
functions of `P.cons_computable`/`P.eq_computable`, and `finter` is `P.inter` (on `Nat.pair`
codes).

The combined index is `w = Nat.pair i j`; in the node I node case the children's results are
read from
the memo table by `listGet`. -/

```

/-! ### Correctness of the decider step (strong induction on the combined code).

Given that `fcons`/`feq`/`finter` correctly decide `D`-consistency / `D`-equality / `D`-
intersection,
the packed triple `gOf (dsharpStep ...)` correctly decides `D`S-consistency, computes the
`D`S-intersection index, and decides `D`S-equality. Proved together by strong induction on
the
combined code `Nat.pair i j`; the node I node case recurses to strictly smaller codes (present
in the
memo table by `pair_lt_pair_of_lt`). -/

# Proposition 7.7 -- Milestone 4: the Example 6.1 combinators are computable

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Proposition 7.7.** For any effectively given domain `D`, the domain `D^S` is also
  effectively
> given, and all the combinators of Example 6.1 prove to be computable.

The "`D^S` is effectively given" half is `Proposition77.dsharp_isEffectivelyGiven`. Here we
  treat,
as Scott does, *a selection* of the Example 6.1 combinators and exhibit them as
`ApproximableMap`s that are `IsComputableMap` with respect to the canonical presentation
`dsharpPresentation P hD`:

* **`inSharpMap`** -- Scott's injection `fun x. x^S : D -> D^S` (Example 6.1's `inSharp`).
  Its
  neighbourhood relation is `X (fun x.x^S) W <-> 0*X subseq W`, i.e. `V_{2n+1} subseq
  V_k`, a recursive slice of
  the inclusion decider, hence r.e. (`inSharp_isComputable`). `inSharpMap_toElementMap` checks
  the
  approximable map really computes `inSharp`.
* **`proj0Map`** -- the first projection `D^S -> D^S` of the pair part (so `proj0(<x,y>^S) =
  x^S`,
  `proj0_toElementMap_pairSharp`). Its relation is `W proj_0 Z <-> Z = Gamma \ / exists P Q
  , W = 1*P U 2*Q /\
  P subseq Z`, i.e. on indices `V_m proj_0 V_k <-> k = 0 \ / (m even, m != 0, V_{p(m
  /2-1)} subseq V_k)`. Both
  disjuncts are recursively decidable, hence r.e. (`proj0_isComputable`).

Each combinator's relation is *recursively decidable* (no unbounded search), so computability
  is
`RecDecidable.re` of a Boolean combination of the inclusion/equality/parity deciders -- exactly
  the
style of Theorem 7.4's `proj_0`/`in_0`. The `ApproximableMap` data is choice-free; only the `
  Prop`
correctness proofs route through `Classical` (set equality over an arbitrary carrier).

# Example 7.8 (Scott 1981, PRG-19, S7) -- the powerset `PN` is effectively given

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Example 7.8.** We have often made reference to the powerset `PN` as a domain and we should
> check here that it is effectively given. ... the neighbourhoods of `PN` are ordered ... in
  the
> partial ordering *converse* to that [of finite sets]. ... What we need first is an
  enumeration of
> all finite sets of integers:
> `E_n = {k ? exists i, j. i < 2? and n = i + 2? + j*2?^+1}`.
> The idea is that `k in E_n` means the exponent `k` occurs in the binary expansion of `n`.
  ... as a
> neighbourhood system `(PN) = {N ? E_n ? n in Nat}`. As the relationship `E_n U E? = E_k`
  is
> recursive, there is no trouble in proving that this is a computable presentation. In this
  system,
> of course, any two neighbourhoods are consistent.

**Formalisation.** Scott's `E_n = {k ? exists i, j. i < 2? /\ n = i + 2? + j*2?^+1}` is
  exactly "`k` is a
set bit of `n`", i.e. `Nat.testBit n k`. The neighbourhoods are the *cofinite* sets
`Nat ? E_n = {k ? not n.testBit k}`, here `nbhd n := {k ? n.testBit k = false}` (so `nbhd 0 =
  Nat = Delta`).

* `nbhd_inter`: `nbhd n I nbhd m = nbhd (n ||| m)` -- the intersection of two cofinite
  neighbourhoods
  removes the *union* `E_n U E? = E_{n ||| m}` of the excluded finite sets. This is Scott's
  `E_n U E? = E_k` with `k = n ||| m` (bitwise OR).
* `nbhd_injective`: `n |-> nbhd n` is one-one (the converse-inclusion ordering Scott mentions
  ; here we
  only need injectivity, from `Nat.eq_of_testBit_eq`).
* `PN` is the neighbourhood system `{nbhd n ? n}` over the token type `Nat`; it is closed under
  intersection because `nbhd n I nbhd m = nbhd (n ||| m)` is again a neighbourhood (so in
  fact *any*
  two neighbourhoods are consistent -- `PN_consistent`).
* `PNpres` is the computable presentation: the enumeration is `nbhd`, the intersection function
  is
  the **choice-free primitive-recursive bitwise OR** `Domain.Recursive.myLor` (`= (* ||| *)`,
  `myLor_eq_lor`), and Scott's relation 7.1(i) `nbhd n I nbhd m = nbhd k <-> (n ||| m) = k`
  is decided
  by `RecDecidable.natEq` (equality of two primitive-recursive functions). Relation 7.1(ii) is
  *always true* (any two neighbourhoods are consistent), so it is trivially recursively
  decidable.
* `PN_isEffectivelyGiven`: `PN` admits a computable presentation.

Everything is choice-free (`subseq {propeq, Quot.sound}`): all the bit-level facts go
  through mathlib's
  `Nat.testBit_lor` / `Nat.eq_of_testBit_eq` (both `[propeq, Quot.sound]`) and the bespoke
  primitive-recursive `myLor`.

# Definition 7.9 (Scott 1981, PRG-19, S7) -- the Smyth power domain `??`

Scott closes Lecture VII with "an example of another kind of domain construct", the
*Smyth Power Domain*. For any neighbourhood system `?` it builds a new system `??` whose
elements behave like sets of elements of `?`.

**Definition 7.9.** For a neighbourhood system `?`,

`?? = { ?_{i<n} (X_i) ? forall i<n. X_i in ? }`,

where the down-set of `X` in `?` is `X = {Y in ? ? Y subseq X}`. The finite unions
can be
*empty* (`n = 0`), giving the neighbourhood `{}`.

```

Two surrounding remarks Scott records as part of the definition:

```
* The construct is made isomorphism-invariant by first preparing `?`: replace it by the
  isomorphic positive system `?? = {X ? X in ?}` (Exercise 1.20). Then `??` is the closure of
  `??` under finite unions.
* `X I Y != {}` iff `{X, Y}` is consistent in `?`, and in that case `X I Y = (X I Y)`.
```

What this file formalizes

Scott's ``X`` of S7 is *exactly* the set ``Exercise 1.20`` already named ``upSet``
`(`{Y in ? ? Y subseq X})``, and the preparation ``??`` is exactly Exercise 1.20's ``powerSystem``
 (here aliased ``dagger``, with the iso ``dagger_isomorphic : ? ~?= ? ??`` reusing
``isomorphic_powerSystem``). On top of those we add:

```
* `PDmem` -- the neighbourhood family of `??` (finite unions of down-sets, indexed by a
  `List` of `?`-neighbourhoods; the empty list realizes the empty union `n = 0`);
* `mem_PDunion` / `PDmem_empty` / `PDmem_upSet` / `PDmem_master` / `PDmem_union` -- the basic
  membership facts that pin the family down (it contains `{}`, every down-set `X`, the
  master `Delta`, and is closed under binary -- hence finite -- union);
* `PDmem_iff_fin` -- the same family written with Scott's `?_{i<n}` (a `Fin n -> Set ?`);
* the two displayed remarks: `upSet_inter_nonempty_iff` (`X I Y != {} <-> {X,Y}`
  consistent)
  and, in the consistent case, `dagger_upSet_inter` (`X I Y = (X I Y) in ??`); the
  unconditional set identity `X I Y = (X I Y)` is Exercise 1.20's `upSet_inter`.
```

This is everything Scott states as part of Definition 7.9 itself; that ``??`` is *itself* a
 neighbourhood system*, effectively given when ``?`` is, is the separate *Proposition 7.10*
 (``Proposition710.lean``). Everything here is choice-free (``subseq`` {proptext, Quot.sound}).

# Proposition 7.10 (Scott 1981, PRG-19, S7) -- `??` is a neighbourhood system, effectively
given

Scott states, right after defining the Smyth power domain `??` (Definition 7.9):

> **Proposition 7.10.** `??` *is a neighbourhood system, and it is effectively given if `?` is
.*

This file delivers both halves.

## Part A -- `??` is a neighbourhood system (`NeighborhoodSystem.PowerDomain`)

Building on `Definition79.lean`'s neighbourhood family `PDmem` (finite unions of down-sets
`?_{X in L} X`), we package it as `V.PowerDomain : NeighborhoodSystem (Set a)` with master `
Delta`. The
content is closure under binary intersection (`PDmem_inter`), which follows from distributing `
I `
over the finite union and the *unconditional* identity `X I Y = (X I Y)` (Exercise 1.20's
`upSet_inter`): each product term `X I Y` is itself in `??` (`PDmem_upSet_inter`) -- it is `(
X I Y)`
when `{X,Y}` is consistent, and `{}` otherwise (the empty term). Deciding *which* requires
testing
`X I Y in ?` over an arbitrary system, so this **one** `Prop`-level step uses `Classical`
(`by_cases`),
exactly as Scott's "throwing out empty terms" anticipates; the *data* of `PowerDomain` (`mem`,
`master`) is choice-free.

## Part B -- `??` is effectively given (`PowerDomain_isEffectivelyGiven`)

Given `P : ComputablePresentation ?`, we enumerate `??`-neighbourhoods by codes of finite lists
of
`?-indices: `Ypd c = ?_{a in decodeList c} X_a`. The two relations of Definition 7.1:

* **ii) consistency is *always true*** -- `{}` in `??` (the empty union, code `0`) is below
every
neighbourhood, so `cons_computable` is the constant decider.
* **i) reduces to *equality of two finite unions of down-sets*, which unfolds (`Ypd_eq_iff`)
to the
nested bounded quantifier
`(forall a in dl c, exists b in dl k, X_a subseq X_b) /\ (forall b in dl k,
exists a in dl c, X_b subseq X_a)` --
recursively decidable by `RecDecidable.bForallList`/`bExistsList` over `P.incl_computable`.

The **intersection function** is a primitive-recursive nested fold over the two index lists,
emitting
`P.inter a b` for the *consistent* pairs `(a, b)` and dropping the rest (the empty terms); its
correctness is the distribution `Y_n I Y_m = ?_{a,b} (X_a I X_b)`. Following the `
funPresentation`
pattern (Theorem 7.5), the presentation takes the component deciders as explicit primitive-
recursive
arguments, so the assembled data is choice-free; `PowerDomain_isEffectivelyGiven` obtains the
deciders
from `P` inside the `Nonempty` proof (extraction into a `Prop` goal needs no choice).

# Definition 7.11 (Scott 1981, PRG-19, S7) -- finite-element joins in `??`

```

Scott introduces the power-domain analogue of a *finite set* of elements.

Definition 7.11. For elements $x_0, \dots, x_{n-1}$ in $|?|$ define

$$\{x_0, \dots, x_{n-1}\} = \{z \text{ in } |??| \mid \exists X_0 \text{ in } x_0 \dots \exists X_{n-1} \text{ in } x_{n-1}. \bigwedge_{i < n} (X_i \text{ subseq } z)\},$$

where X is the principal filter of X in $?$. Scott also notes the equivalent formulation

$$\text{forall } i < n. X_i \text{ in } z \text{ (read with } X_i \text{ identified with the down-set } X_i \text{ in } ??).$$

On finite elements X of $|?|$, $\{X\}$ is the principal filter (X) of $??$ (Prop 7.12).

What this file formalizes

Building on `Proposition710.lean`'s `PowerDomain`, we package Scott's join as a filter

$$\text{PDfinJoin } xs : V.\text{PowerDomain.Element} \text{ for } xs : \text{Fin } n \rightarrow V.\text{Element} \text{ (} n = 0 \text{ gives False)}.$$

Membership is the down-set form of Scott's union condition:

$$W \text{ in } \{x_0, \dots, x_{n-1}\} \iff \exists (X_i \text{ in } x_i). \text{PD.mem } W \wedge \text{forall } i. X_i \text{ subseq } W,$$

equivalently $\text{PD.mem } W \wedge \bigwedge_{i < n} X_i \text{ subseq } W$ for some choice of representatives. The

singleton

$$\text{PDsingleton } x \text{ is the unary join; on principal filters, } \text{PDsingleton } (X) = (X).$$

# Proposition 7.12 (Scott 1981, PRG-19, S7) -- the finite join map on `??`

Scott states, right after Definition 7.11:

> Proposition 7.12. The mapping `fun x_0, ..., x_{n-1}. {x_0, ..., x_{n-1}} : D? -> ?D`
  is approximable
> and is computable if `D` is effectively given. Moreover, the map `fun x. {x}` shows that
> `D ? ?D`, and we also have `{x_0, ..., x_{n-1}} = {x_0} I ... I {x_{n-1}}` as an
  intersection of filters.

This file delivers Parts A, B, and D in full. Part C (`D ? ?D`) turns out to be false in
general under the present definition of `??` (Definition 7.9), and we formalize a
counterexample instead -- see `Counterexample712C` at the bottom.

## Part A -- the singleton map `fun x. {x}` is approximable

Built by Exercise 2.8's `ofMono` from its values on principal inputs `X |-> {X}` (`
PDsingleton`).
Monotonicity uses that `{X}` is blunter than `{X}` when `X` subseq `X`.

On finite elements, `{X} = (X)` in `??` (`PDsingleton_principal`): the principal filter of the
down-set token `X`.

## Part B -- the intersection law `{x, y} = {x} I {y}` (hence the general fold)

Scott's proof on principal inputs `{X} I {Y} = {X, Y}` unfolds to
`X I Y = (X I Y)` via `upSet_inter`, then to the binary join. The general law
`PDfinJoin_inter` follows by induction on `n`.

## Part C -- `D ? ?D` is FALSE in general (counterexample)

Scott's closing remark "`fun x. {x}` shows `D ? ?D`" does not hold for an arbitrary
neighbourhood
system `?` once `??` is taken to include the empty union `{}` (Definition 7.9's `n = 0`
case,
`PDmem_empty`). The obstruction is structural:

* `??` is unconditionally closed under intersection (`PDmem_inter`; the empty union always
  supplies the missing consistency witness), so `|??|` has a greatest element -- the
  improper
  filter consisting of all `??`-neighbourhoods (`Counterexample712C.hasTop_of_inter_closed`).
* Any subsystem `D'` of `??` inherits that unconditional  $\cap$ -closure (Definition 6.10's
  `inter_closed`), so `|D'|` also has a greatest element.
* `D ? ?D` means `D` is a subsystem of `D'` for some `D'` of `??`, and `?` is an order-isomorphism of
  element
```

```

lattices, which transports "has a greatest element" back to  $|D|$ .

So  $D \models \text{?}$  forces  $|D|$  to have a greatest element. But the two-point flat domain  $\text{Vshape}$ 
(neighbourhoods  $\Delta = \{\text{true}, \text{false}\}$ ,  $\{\text{true}\}$ ,  $\{\text{false}\}$ , with  $\{\text{true}\} \cap \{\text{false}\} = \{\}$ 
notin  $\text{?}$ ) has two
incomparable maximal elements and hence no greatest element. Therefore
 $\text{Vshape} \models \text{Vshape.PowerDomain}$  (Counterexample712C.vshape_not_trianglelefteq_powerDomain).

This is exactly the wall the projection-pair route hit: a monotone (approximable) retraction
 $\text{?} \rightarrow \text{?}$  would have to send  $\text{top}_{\text{?}} = \{\}$  to an upper bound of all of  $|?|$ , i.e. to a
greatest
element of  $|?|$ , which need not exist. Scott's claim is correct precisely when  $|?|$  has a top
(equivalently  $\text{?}$  has a least neighbourhood), e.g. when  $\{\}$  in  $\text{?}$ ; the singleton injection
itself
(PDsingletonApproxMap) is the surviving "one half" of the would-be projection pair.

## Part D -- computability when  $D$  is effectively given

Against PDPresentation (Proposition 7.10), the neighbourhood relation for  $\text{fun } x. \{x\}$  is
 $\exists b \text{ in } \text{dl } k, X_n \text{ subseq } X_b \text{ -- a bounded } \exists \text{ over } \text{P.incl\_computable}$  (singleton_isComputable).
The binary join map on  $D \times D$  is obtained from two independent singleton conditions
(PDfinJoinApproxMap_2_isComputable); the general  $n$ -ary case reduces to the intersection law
.

# Exercise 7.13 (Scott 1981, PRG-19, S7) -- effectively given domains <-> an `INCL` relation
on `Nat`

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.13.** Show that an effectively given domain can always be identified with a
> relation
> `INCL(n, m)` on integers, where the two derived relations
>
> * `CONS(n, m) : <-> exists k. INCL(k, n) /\ INCL(k, m)` (consistency),
> and
> * `MEET(n, m, k) : <-> forall j. (INCL(j, k) <-> INCL(j, n) /\ INCL(j, m))` (binary
> meet)
>
> are both recursively decidable, and where the axioms hold:
>
> * (i) `forall n. INCL(n, n)` (reflexive)
> * (ii) `forall n m k. INCL(n, m) /\ INCL(m, k) -> INCL(n, k)` (transitive)
> * (iii) `exists m forall n. INCL(n, m)` (a greatest code --
> the master `Delta`)
> * (iv) `forall n m. CONS(n, m) -> exists k. MEET(n, m, k)` (consistent pairs
> have a meet)
>
> (Hint: consider the neighbourhood system `? = { {m ? INCL(m, n)} ? n }`. Is this essentially
> any
> effectively given system?)

## What this file proves

`INCL(n, m)` is the integer image of `X_n subseteq X?`. The exercise is an **equivalence**,
formalized here
in both directions plus the two round-trips:

* **`InclStructure`** -- the abstract data Scott asks for: a relation `INCL` with recursively
decidable
`INCL`/`CONS`/`MEET`, and axioms (i)-(iv). Following the project's `ComputablePresentation`
convention (which carries `inter` as primitive-recursive *data* rather than recovering it by
an
unbounded ?-search), we carry the *witnesses* of (iii)/(iv) as a master index `topIdx` and a
primitive-recursive meet function `meetIdx`; the literal existential axioms (iii)/(iv) are
then

```

```

recovered as theorems (`axiom_iii`/`axiom_iv`).
* **(?) `InclStructure.toSystem` / `toPresentation` / `toSystem_isEffectivelyGiven`** -- Scott's
  hint
system `S_n = {m ? INCL(m, n)}` is a neighbourhood system and is *effectively given*. The
  crux is
`toNbhd_subset_iff : S_n subseq S? <-> INCL(n, k)` ( <- by transitivity (ii), ->
  because `n` in `S_n` by
  reflexivity (i)); relation 7.1(i) is `MEET` (`toNbhd_inter_eq_iff`), 7.1(ii) is `CONS`.
* **(> ) `ofPresentation`** -- every effectively given domain yields such an `InclStructure`
  with
  `INCL n m := X_n subseq X?`. The only non-trivial decidability is `MEET`: on an
    effectively given system
  `MEET(n, m, k) <-> X_n I X? = X?` (`meet_iff_interEq`; => uses that a `MEET` witness
    makes `(n, m)`
  consistent, hence `X_n I X?` in `?` by `inter_mem`, hence enumerated by `surj`), so `MEET`
    is decided
  by the presentation's `interEq`.
* **Round-trip A `ofPresentation_toPresentation_INCL`** -- `INCL` |-> ? |-> `INCL` recovers `
  INCL` exactly.
* **Round-trip B `reconstruct_isomorphic`** -- `toSystem (ofPresentation P) == ? V`: the
  reconstructed
  system *is* (domain-)isomorphic to the original, answering Scott's "Is this essentially any
  effectively given system?" with **yes**. (Exercise 7.18's *effective* isomorphism would
    tighten
  "essentially" to the effective level.)

```

Choice discipline

The `INCL`/`CONS`/`MEET` deciders and the presentation *data* are built on the choice-free
`Recursive.lean` layer and audit `subseq {propxt, Quot.sound}`. `Set`-equality/membership
reasoning over
the arbitrary carrier `a` (the `MEET` <-> `interEq` proof, the isomorphism's filter/`OrderIso`
laws)
pulls `Classical.choice` at the `Prop` level only -- the same pattern as Theorems 7.4/7.5/7.10.

/-- **Exercise 7.13 -- the abstract data.** A relation `INCL : Nat -> Nat -> Prop` together
with the
witnesses and decidability/axiom data Scott requires. The derived relations are
`CONS`/`MEET` (below); the literal existential axioms (iii)/(iv) are `axiom\_iii`/`axiom\_iv`.

We carry `topIdx` (a master code) and a primitive-recursive `meetIdx` as *data* -- exactly
mirroring
`ComputablePresentation`, which carries its `inter` function as primitive-recursive data rather
than
recovering it by an unbounded search. This is the faithful "effective" reading of axioms (iii)
/(iv).

# Exercise 7.14 (Scott 1981, PRG-19, S7) -- the r.e. facts after Definition 7.2

> **Exercise 7.14.** (For recursive-function theorists.) Prove the statements after definition
  7.2
> about the existence of primitive recursive functions for showing things recursively
  enumerable.
> (Recall that a non-empty set is r.e. iff it is the range of a primitive recursive function.)
  Show
> also that every computable element  $y$  in  $|?|$  can be written
>  $y = ? \{Y_{\{t(i)\}} ? i \text{ in } \text{Nat}\}$ , where  $t : \text{Nat} \rightarrow \text{Nat}$  is primitive recursive and where we
  may assume
>  $Y_{\{t(i+1)\}} \text{subseq } Y_{\{t(i)\}}$  for all  $i \text{ in } \text{Nat}$ .

```

This exercise has two halves.

Half 1 -- "a non-empty set is r.e. iff it is the range of a primitive recursive function"

Scott's prose after Definition 7.2 reads: "What it means to be recursively enumerable is that there is a primitive recursive function (hence, a total function) $r : \mathbb{N} \rightarrow \mathbb{N}$ such that $y = \{Y_{\{r(i)\}} \mid i \in \mathbb{N}\}$ " and, for a computable map, $f = \{(X_{\{s(i)\}}, Y_{\{r(i)\}}) \mid i \in \mathbb{N}\}$ for a suitable pair of primitive recursive functions s and r ." This is exactly the classical characterization of non-empty r.e. set = range of a primitive recursive function. Our choice-free model of r.e. is `Domain.Recursive.REPred p := exists q, RecDecidable q /\ forall n, p n <-> exists i, q <i,n>` (projection of a recursively decidable relation), so we prove both directions against it:

```
* `reprd_range_primrec` -- the **range** of a primitive recursive `r` is r.e. (the relation
`r i = n` is recursively decidable by `RecDecidable.natEq`, and `exists i, r i = n` is its
projection);
* `reprd_exists_primrec_range` -- every **non-empty** r.e. set is the range of a primitive
recursive
function. From a witness `a` in `p` and the decider `qc` of the underlying relation, the
function
`r w := selectFn (isOne (qc w)) w.2 a` enumerates `p`: on a witnessing code `w = <i,n>` (
where
`qc w = 1`) it returns `n`, and it falls back to the fixed `a` in `p` otherwise, so its range
is
exactly `p`. (The fall-back `a` is precisely why *non-emptiness* is needed.)
* `reprd_2_exists_primrec_enum` -- the map form: a non-empty r.e. *relation* `p n m` is
enumerated by
a pair of primitive recursive functions `s, r` with `p n m <-> exists i, s i = n /\ r i
= m` (split the
range function of the `Nat.pair`-coded relation into its two projections). This is Scott's
`f = {(X_{s(i)}, Y_{r(i)})}`.
```

Half 2 -- every computable element is a decreasing union of finite (principal) elements

```
`computableElement_eq_decreasing_iUnion_principal`: for a computable element `y` of an
effectively
given `W` (IsComputableElement Q y, i.e. the index set  $\{m \mid Y_m \in y\}$  is r.e.), there is a
**primitive recursive**  $t : \mathbb{N} \rightarrow \mathbb{N}$  with
* (decreasing)  $Q.X(t(i+1)) \subseteq Q.X(t(i))$  for all  $i$ ;
* (union)  $y \text{ mem } Z \iff \exists i, (Y_{\{t(i)\}} \text{ mem } Z)$ , i.e.  $y = \bigcap_i Y_{\{t(i)\}}$  (Factoid
1.7b form).
```

The index set is non-empty (it contains the master Δ , since every filter contains Δ), so Half 1 gives a primitive recursive enumeration r_0 of all of y 's indices. To force the approximations to decrease, we take running intersections: $t_0 = r_0 0$, $t(i+1) = \text{inter}(t(i), r_0(i+1))$, using the presentation's primitive-recursive intersection function `Q.inter`. Each $Y_{\{t(i)\}}$ is the meet of the first $t(i)+1$ members of y , hence still in y (filters are $\cap$ -closed) and $\subseteq Y_{\{t_0(i)\}}$, which is what makes the union still equal to y while being a decreasing chain.

Choice discipline. Half 1 is built only on the choice-free `Recursive.lean` layer and audits `subseq {proptext, Quot.sound}`. Half 2's *data* (the function `t` and its primitive recursiveness) is also

```

choice-free; the `Prop`-level union/membership reasoning over `Set b` may pull `Classical.
choice`
(the usual `Set`-equality pattern of Lecture VII), flagged in the checkpoint.

/-- **A non-empty recursively enumerable set is the range of a primitive recursive function.**
This
is the precise content of Scott's prose after Definition 7.2 ("there is a primitive recursive
`r`
with `y = {Y_{r(i)}}`"). Given a witness `a` in `p` and the `{0,1}` decider `qc` of the
relation `q`
underlying `p` (`p n <-> exists i, q <i,n>`), the function `r w := selectFn (isOne (qc w)) w
.unpair.2 a` enumerates
`p`: on a code `w = <i,n>` with `q <i,n>` it returns `n`, otherwise it returns the fixed `a`.
Its
range is exactly `p` (the fall-back `a` covers the codes that do not witness anything -- this
is where
non-emptiness is used). -/
theorem repred_exists_primrec_range {p : Nat -> Prop} (hp : REPred p) {a : Nat} (ha : p a) :

# Exercise 7.15 (Scott 1981, PRG-19, S7) -- effective givenness of `?`, `?`, `D` inf `

> **EXERCISE 7.15.** Finish the proof of 7.4 and establish similar results for the constructs
> `(D_0 ? D_1)`, `(D_0 ? D_1)` and `D` inf `. Take into account the various appropriate
  combinators.

Theorem 7.4 (the separated `+` and `x`) is already complete in `Theorem74.lean`, with all
combinators (`proj_i`, `in_i`, `out_i`, `

```

```

`inter` (that is a project strengthening, needed only for the function space, Theorem 7.5). So
we
introduce Scott's literal notion as `ScottPresentation` and prove `?`/`?` effectively given
with
respect to it. Both of (i),(ii) *are* recursively decidable for `?`/`?` -- they reduce to
boolean
combinations of the components' relations together with the (recursively decidable) properness
tests.

**Choice discipline.** `ScottPresentation` and the `D` inf ` results are choice-free. For
`?`/`?` the
*only* classical input is the **enumeration** `X`, which must branch on the (set-equality)
properness
test; we localise `Classical.choice` to that one field (`smashEnum`/`osumEnum`). The
recursively
decidable relations (i),(ii) are proved **choice-free** by deconstructing the components'
deciders.

`D` inf = iterSys D` (Exercise 3.16) is *uniform* (every cylinder is a genuine member, no
deletion), so
it admits a full `ComputablePresentation` and is treated choice-free in the existing interface,
with
the coordinate-projection combinators `projN`/`head` computable.

/-! ## The smash product `?_0 ? ?_1` is effectively given (Scott's Definition 7.1)

`smash V_0 V_1` (`Exercise510.lean`) over `a ? b` has neighbourhoods the master `prodNbhd
Delta_0 Delta_1`
together with the *proper* products `prodNbhd X Y` (`X != Delta_0`, `Y != Delta_1`). We
enumerate it by pairs of
component indices, re-routing improper pairs to the master. The re-routing is the only
classical
input (it branches on the set-equality `X_n = Delta_0?`). The two relations (i),(ii) are choice
-free
recursively decidable. -/

/-! ### Projections and the strict pairing for `?` (the `x`-analogue combinators).

The smash product carries the same *projections* `proj_0`/`proj_1` as the separated product (a
smash
member is still a product neighbourhood `prodNbhd A B`, and `Sum.inl ^-1' (prodNbhd A B) = A`)
and a
*strict pairing* `? : ?_2 -> ?_0 ? ?_1`. Because the smash deletes the improper
products, the
pairing forces *proper* image factors and otherwise lands on the master. All three are
computable:
the projections by `smashEnum_eq_eff` + `incl_computable`, the pairing by `a`,`b`'s r.e.
relations on
the (raw) codomain coordinate indices together with the codomain properness tests. -/

/-! ### The appropriate combinator for `?` : the functorial action `f ? g`.

The smash product is a (bi)functor; `smashMap f g : ?_0 ? ?_1 -> ?_0' ? ?_1'` is the
  coalesced analogue
of Theorem 7.4's `f x g` (`prodMap`). Because the smash collapses bottoms, the relation
  forces
*proper* image factors (`A' != Delta_0'`, `B' != Delta_1'`) and otherwise lands on the
  master (the strict
collapse). It is a genuine `ApproximableMap` and is **computable**: on the effective product
  indices
its relation decodes to `f`'s and `g`'s r.e. relations together with the codomain properness
  tests. -/

/-! ## The coalesced sum ` $?_0 ? ?_1$ ` is effectively given (Scott's Definition 7.1)

`?_0 ? ?_1` (Exercise 6.21, here over `Option (a ? b)`) is the separated sum `+` with the *
improper*
tagged copies ` $0\Delta_0$ `, ` $1\Delta_1$ ` deleted (the two bottoms identified). As with `?`, the
enumeration must
re-route improper copies to the master (the sole classical input), while the relations (i),(ii)
are
choice-free recursively decidable. -/

/-! ### The appropriate combinators for `?` : injections `in_0`/`in_1` and projections `out_0`/`
out_1`.

These are the coalesced analogues of Theorem 7.4's separated-sum combinators (`Exercise318`'s
`inMap_0`/`outMap_0`), re-housed over `osum` (whose members are the *proper* tagged copies +
master).

Each is a genuine `ApproximableMap` and is **computable** (`IsComputableMapS`): the
neighbourhood
relations decode, tag-by-tag, to slices of the components' `incl_computable` together with the
recursively-decidable properness tests `proper_0_dec`/`proper_1_dec`. -/

variable {h_0 h_1}

/-- An `osum`-member containing `inj_0 Delta_0` is forced to be the master (the bottom-collapse
: the only
proper copy `supseteq inj_0 Delta_0` would need `Delta_0 subseteq X` with `X != Delta_0`)

/-! ### The appropriate combinator for `?`: the functorial action `f ? g`.

`osumMap f g : ?_0 ? ?_1 -> ?_0' ? ?_1'` is the coalesced analogue of Theorem 7.4's `f + g`
(`sumMap`).
The coalesced relation additionally forces the image copy to be *proper* (`Y' != Delta`);
otherwise the
strict collapse routes to the master. It is a genuine `ApproximableMap` and is **computable**.

end Coalesced

/-! ## The infinite iterate `D` inf ` is effectively given (full `ComputablePresentation`)

`D` inf = iterSys V` (Exercise 3.16) is *uniform*: a neighbourhood `W` is a member iff every
fiber is a
`V`-neighbourhood and all but finitely many fibers equal `Delta`; there is **no deletion/
collapse** as in
`?`/`?`. So it admits the project's *full* `ComputablePresentation` -- and **choice-free**.

**Coding.** Given a presentation `P` of `V`, a `D` inf -code `t : Nat` codes the finite list
of fiber
indices `[i_0, i_1, ..., i_{?-1}]` (`Recursive.decodeList`); fiber `j` of the enumerated
neighbourhood is
`P.X (iterIdx t j)`, where `iterIdx t j = nthCode t j P.masterIdx` reads the `j`-th list entry,
defaulting to `P.masterIdx` (so all but finitely many fibers are `Delta`). The intersection
function is
built by `tabCode`-tabulating `P.inter` coordinate-wise. All three relations and the `inter`
function
are primitive recursive because they are bounded computations over `nthCode`/`tabCode`/`P`'s
data. -/

# Exercise 7.16 (Scott 1981, PRG-19, S7) -- `curry` as a neighbourhood relation

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.16.** Let  $D_0 = \{X_n\}$ ,  $D_1 = \{Y?\}$  and  $D_2 = \{Z?\}$  be three effectively
  given domains.
> Complete the proof of 7.5 by writing out `curry` as a relation between neighbourhoods. Is it
  a
> recursive set or only a recursively enumerable set?

Theorem 7.5 (`Theorem75.lean`) states that `eval` and `curry` are *computable* combinators.
  Scott
writes out `eval` explicitly and shows its neighbourhood relation is a **recursive** (decidable
  ) set;
he leaves `curry` "to the exercises". This file completes that: it writes out the `curry`
**combinator**

  `curry : (?_0 x ?_1 -> ?_2) -> (?_0 -> (?_1 -> ?_2))`

as an approximable mapping between the two function-space domains, gives its neighbourhood
  relation,
and shows that relation is **recursive** (a recursively *decidable* set), not merely r.e. --
  exactly as
for `eval`.

## The combinator and its neighbourhood relation

`curry` (Theorem 3.12, `FunctionSpace.curry`) is the function on *maps*  $g \mapsto \text{curry } g$ . As
  Scott's
Theorem 3.12 shows, it is an order-isomorphism  $|?_0 \times ?_1 \rightarrow ?_2| \cong |?_0 \rightarrow (?_1 \rightarrow ?_2)|$ , so
  by Theorem 2.7
(`ofIso`) it itself comes from an approximable mapping between the function-space domains --
  already
built as `curryC V_0 V_1 V_2` in `Table55.lean` (with faithfulness `curryC_toApproxMap`). We
  reuse it
and **write out** its neighbourhood relation (`curryComb_rel`):

  `G curryC H ? G, H neighbourhoods and forall g in G, curry g in H`,

which, unfolded to the explicit step-entries of the two presentations, reads:

  `G curryC H ? for every entry `[X?, W?]' of `H` and every step `[Y?_i, Z?_i]' of `W?`,
    G subseq [X?, Y?_i, Z?_i]`.

Each  $G \text{ subseq } [X?, Y?_i, Z?_i]$  is **function-space inclusion** in  $(?_0 \times ?_1 \rightarrow ?_2)$ ,
  which is recursively
*decidable* (`ComputablePresentation.incl_computable`), and the surrounding quantifier is a *
  bounded*
`forall` over the coded entry-lists. Hence the relation is **recursive** -- the answer to
  Scott's question.

/-! ### The `curry` combinator as an approximable mapping (Theorem 2.7 / Theorem 3.12).

The combinator `curry : (?_0 x ?_1 -> ?_2) -> (?_0 -> (?_1 -> ?_2))` is already built in `
Table55.lean` as
`curryC V_0 V_1 V_2 = ofIso (curryIso V_0 V_1 V_2)` (Theorem 2.7 applied to Theorem 3.12's
order-iso
`curryIso`), with faithfulness `curryC_toApproxMap`. We reuse it and write out its
neighbourhood
relation. -/

/-- `curryIso V_0 V_1 V_2` sends a filter `x` to the filter of the curried least map (by
definition). -/
theorem curryIso_apply (x : (funSpace (prod V_0 V_1) V_2).Element) :
  curryIso V_0 V_1 V_2 x = toFilter (curry (toApproxMap x)) := rfl

/-! ### Writing out `curry` as a relation between neighbourhoods. -/

/-- The least map of a function-space neighbourhood `G` -- `toApproxMap G` -- belongs to `G`.
-/
theorem toApproxMap_principal_mem {G : Set (ApproximableMap V_0 V_1)}

    exact <hH, hall _ (toApproxMap_principal_mem hG)>

/-! ### Recursive (not merely r.e.): the combinator's neighbourhood relation is decidable.

Following the structure of `eval` (Milestone 7 of `Theorem75.lean`, where Scott observes `eval`
is a
*recursive* set), we show that `curry` -- read off the explicit step-entries of the two
presentations --
is a **recursively decidable** relation between codes. The crux: each clause `G subseteq [<X

```

```

    ?Y?_i>,Z?_i]` is
function-space inclusion in `(?_0 x ?_1 -> ?_2)`, recursively *decidable* via `incl_computable`
`; the step
`[<X?,Y?_i>,Z?_i]` is a one-entry function-space neighbourhood (`Xenum_singleton`); the
surrounding
quantifiers are *bounded* `forall` `s` over the coded entry-lists (`RecDecidable_2.bForallList`).
-/

/-- The code of the one-entry function-space neighbourhood `[<X_{e.1}, X_{e'.1}>, X_{e'.2}]` of
`(?_0 x ?_1 -> ?_2)` (a `Xenum`-singleton over the product presentation). -/
def curryStepCode (a e' : Nat) : Nat :=
  Nat.pair (Nat.pair (Nat.pair a e'.unpair.1) e'.unpair.2) 0 + 1

theorem primrec_curryStepCode {a e : Nat -> Nat} (ha : Nat.Primrec a) (he : Nat.Primrec e) :
  Nat.Primrec (fun w => curryStepCode (a w) (e w)) := by
  have h1 : Nat.Primrec (fun w => (e w).unpair.1) := Nat.Primrec.left.comp he
  have h2 : Nat.Primrec (fun w => (e w).unpair.2) := Nat.Primrec.right.comp he
  refine (Nat.Primrec.succ.comp (((ha.pair h1).pair h2).pair (Nat.Primrec.const 0))).of_eq
    (fun w => ?_)
  rfl

/-- **Exercise 7.16 -- `curry` is a *recursive* set.** Relative to the function-space
presentations
`PA` of `(?_0 x ?_1 -> ?_2)` and `PB` of `(?_0 -> (?_1 -> ?_2))` (and the inner one `Pc` of `(?_1 -> ?_2)`) built by
Theorem 7.5, the `curry` combinator's neighbourhood relation is **recursively decidable**:

`Xenum_PA n curryComb Xenum_PB m ? gNb m = 1 -> forall e in ?m?, gNc e_2 = 1 ->
forall e' in ?e_2?, X_PA n subseq X_PA (
  curryStepCode e_1 e')`,

a bounded double-`forall` over the coded entry-lists of the recursively *decidable* function-
space
inclusion. So `curry` is a recursive set -- exactly as for `eval`. -/

# Exercise 7.17 (Scott 1981, PRG-19, S7) -- Part 1: all the Example 6.1 combinators for  $D^S$ 

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.17.** Complete the proof of 7.7 for showing that  $D^S$  is effectively given if  $D$  is.
> Include all the combinators of 6.1. Prove also that if  $E$  is effectively given and  $u : D \rightarrow E$  and
>  $v : E \times E \rightarrow E$  are computable, then the unique strict mapping  $g : D^S \rightarrow E$ , where
>  $g(\text{in } x) = u(x)$  and  $g(\text{pair}(y, z)) = v(g(y), g(z))$ , is a computable mapping.

(Scott's text prints "6.2"; the construct  $D^S$  and its combinators are Example **6.1**, and
7.7 is
itself stated "all the combinators of Example 6.1", so we read it as 6.1.)

`Proposition77.dsharp_isEffectivelyGiven` already gives the first clause ( $D^S$  effectively
given), and
`Combinators77.lean` did **a selection** of the combinators ( $\text{inSharp} = \text{fun } x. x^S$ , and the
pair-part
first projection  $\text{proj}_0$ ). **This file finishes Part 1** -- the full set of Example 6.1's
algebra
combinators, each as an ApproximableMap that is IsComputableMap w.r.t. the canonical
presentation(s):

**`proj1Map`** -- the second projection of the pair part,  $\text{proj}_1 : D^S \rightarrow D^S$ 
( $\text{proj}_1 \text{ toElementMap\_pairSharp} : \text{proj}_1(\langle x, y \rangle^S) = y$ ); computable via the right-child
reindex
( $\text{proj}_1 \text{ isComputable}$ ). The exact mirror of Combinators77.proj0Map.
**`pairSharpMap`** -- Scott's pairing constructor  $\text{pair} : D^S \times D^S \rightarrow D^S$  as a joint
approximable
map out of the product  $\text{prod } (D^S) (D^S)$  ( $\text{pairSharpMap\_toElementMap} : \text{pair}(x, y) \mapsto \langle x, y \rangle^S$ ,
i.e. Example61.pairSharp); computable because its index relation is exactly
 $V_{\{2 \leq a, b \leq 2\}} \text{ subseq } V_k$  ( $\text{pairSharp\_isComputable}$ ), a recursive slice of  $D^S$ 's
inclusion decider.

Together with inSharpMap/proj0Map this is the complete combinator set of the domain
equation
 $D^S \simeq D + (D^S \times D^S)$ : the two injections in, pair and the two pair-part projections
.

The **second clause** of 7.17 (the universal strict catamorphism  $g : D^S \rightarrow E$  and its
computability)
is a separate, larger development handled subsequently.

As in Combinators77.lean, all ApproximableMap **data** and the **faithfulness** theorems
are
```

```

choice-free `subseq {propext, Quot.sound}`; only the `IsComputableMap` proofs route through
`Classical`
(set reasoning over the arbitrary carrier `a`, inherited from `incl_computable`).

# Exercise 7.17 (Scott 1981, PRG-19, S7) -- Part 2: the universal strict mapping `g : D^S ->
  E`

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.17.** ... Prove also that if `E` is effectively given and `u : D -> E` and
> `v : E x E -> E` are computable, then the unique strict mapping `g : D^S -> E`, where
> `g(in x) = u(x)` and `g(pair(y, z)) = v(g(y), g(z))`, is a computable mapping.

This is the *catamorphism* (fold) out of the tree algebra `D^S ~= D + (D^S x D^S)` (Example
  6.1) into a
`T`-algebra structure `(E, [u, v])`. We build `g` directly as a neighbourhood relation `GRel u
  v`,
defined by recursion on the three `D^S`-neighbourhood shapes:

* `Gamma          |-> Delta_E` (strict: `False |-> False`);
* `0*X           |-> u`s relation on `X`;
* `1*P U 2*Q      |-> exists Z_1 Z_2, P g Z_1 /\ Q g Z_2 /\ <Z_1,Z_2> v Z`.

There is no separate "top" clause: because `u` and `v` are approximable (they relate `Delta
  |-> Delta`),
`GRel u v W Delta_E` already holds for every `W` in `?^S` (`gRel_master`). The three clauses
  give an
honest `ApproximableMap` (`gMap`), with the two defining equations
`gMap_in : g(in x) = u(x)` and `gMap_pair : g(pair y z) = v(<g y, g z>)`, and strictness
`gMap_strict`.

The computability (`gMap_isComputable`) is the heart of the exercise. The index relation
`R m k := GRel u v (V_m)(Y_k)` (`V` = `Vsharp` the `D^S` enumeration, `Y` = `Q`'s enumeration
  of `E`)
satisfies the recursive characterisation `gRel_index_*`. We realise it as the recursively-
  enumerable
existential `exists cert` over a stack-machine certificate: a derivation is a postorder *
  program* of
push/pop instructions verified by a single primitive-recursive `foldCode`, exactly the device
  used for
`fix` in Theorem 7.6. (A per-`Vsharp`-index memo -- as in `dsharpStep` -- does not work
  here, since
`R` is a genuine relation: the same sub-neighbourhood may be folded to different outputs in
  different
parts of the tree, so the certificate must mirror the derivation tree.)

Data and the two equations are choice-free `subseq {propext, Quot.sound}`; the `
  IsComputableMap` proof and
the inversion lemmas route through `Classical` (`Set` reasoning over the arbitrary carriers `a
  `, `b`),
as everywhere in this layer.

/#! ### The stack-machine / course-of-values certificate evaluator.

`R n m := GRel u v (V_n)(Q_m)` (`V` = `Vsharp`, `Q` = `Q.X`) satisfies the recursion: `n = 0`
folds to `Delta_E`; `n = 2a+1` folds via `u`; `n = 2a+2` is `exists Z_1 Z_2, V_{a.1} g Z_1 /\
V_{a.2} g Z_2 /\
<Z_1,Z_2> v Q_m`. A *derivation* is a finite tree (the same `V` may fold to *different* outputs
in
different positions, so the witness must mirror the tree). We encode it as a single `cert` and
verify
it with the `Proposition77` memo `gOf`/`rtbl` over `w = <v, cert>`: at each node the two
children's
results (`okBit`, `outIdx`) are read from the memo table by `listGet`. The step is fed the four
primitive-recursive `{0,1}`/index functions `fe` (`Q`-equality-to-`Delta`), `fU`/`fV` (the
deciders of
`u`/`v`'s r.e. relations), and `mIdx` (`Q`'s master index). -/

end Computability

/-! ### Computability of `g`. -/

/-- **Exercise 7.17 (Part 2) (Scott 1981, PRG-19).** If `E` is effectively given (presentation
`Q`) and
`u : D -> E`, `v : E x E -> E` are computable, then the unique strict catamorphism `g : D
^S -> E`
(`gMap`) is computable.

The index relation `X_n g Y? = GRel u v (V_n)(Y?)` is realised as the recursively-enumerable
existential
`exists cert, gEval<n,cert>.ok = 1 /\ Y_{cert.out} = Y?` over the primitive-recursive
certificate evaluator
`gEval`. Soundness (`gEval_sound`) and completeness (`gEval_complete`) of the certificate give
the
equivalence; the deciders `fe`/`fU`/`fV` are read off `Q.eq_computable` and the r.e. relations
of
`u`/`v`. -/

# Exercise 7.18 (Scott 1981, PRG-19, S7) -- effective isomorphism;  $D^\infty \approx (D^\infty)^\infty$ 
  is effective

> **EXERCISE 7.18.** Two effectively given systems  $D$  and  $E$  are effectively isomorphic iff
...
> (complete the sentence!). Show that if  $D$  is effectively given then the isomorphism
>  $D^\infty \approx (D^\infty)^\infty$  is effective.

## Completing the sentence (Definition of effective isomorphism)

Scott's Definition 1.9 says  $D \approx E$  means there is a one-one, inclusion-preserving
correspondence
 $|D| \ni \phi \mapsto |E| \ni \psi$ ; Theorem 2.7 shows every such correspondence is induced by an approximable map.
The
effective refinement is the obvious one: the isomorphism, together with its inverse, must be
computable in the sense of Definition 7.2. We package this symmetrically as a pair of
mutually
inverse computable approximable maps:

* EffectiveIso P Q -- relative to computable presentations  $P$  of  $D$  and  $Q$  of  $E$ , a pair

```

```

`toMap : D -> E`, `invMap : E -> D` of approximable maps, both computable (`
  IsComputableMap`),
  that are mutually inverse (`invMap comp toMap = I_D` and `toMap comp invMap = I_E`).
* `EffectivelyIsomorphic P Q := Nonempty (EffectiveIso P Q)`.

Every effective isomorphism is in particular a domain isomorphism (`EffectiveIso.toDomainIso`,
`EffectivelyIsomorphic.isomorphic`), so this tightens Scott's `~=` (and, via Exercise 7.13's
`reconstruct_isomorphic`, tightens its "essentially the same").

## `D` inf  ~=  (D` inf )` inf ` is effective

`D` inf  = iterSys V` (Exercise 3.16) has token type `Nat x a` and elements the infinite
sequences
`<x_k>` of `|D|`-elements (`iterSeqEquiv`). `(D` inf )` inf  = iterSys (iterSys V)` has token
type
`Nat x (Nat x a)` and elements the double sequences `double-indexed fiber of a `(D` inf )` inf  -neighbourhood `S` is
`fiber2 S i j = fiber (fiber S i) j`:

* `Fmap.rel W S <-> forall i j, fiber W (pair i j) subseteq fiber2 S i j`;
* `Gmap.rel S W <-> forall k, fiber2 S (unpair k).1 (unpair k).2 subseteq fiber W k`.

They are mutually inverse (`Gmap.comp Fmap = I`, `Fmap.comp Gmap = I`), proved directly on the
relations using the reindexing constructions `reindexF`/`reindexG`. Each is recursively
decidable
(hence computable) over `iterPresentation P` / `iterPresentation (iterPresentation P)`: the
relation
on codes reduces to a bounded check of `incl_computable` over the coordinates `(i,j)` (resp.
`k`)
that the codes actually constrain (everything beyond the coded fiber lengths is `Delta`, so
trivially
satisfied). The whole development is choice-free (`subseteq {proptex, Quot.sound}`): the one
place a finite
maximum is needed (the cofinite bound of `reindexG`) is obtained by a `Prop`-level induction,
not by
choosing witnesses.

# Exercise 7.19 (Scott 1981, PRG-19, S7) -- `D |-> ?D` is a functor

> **EXERCISE 7.19.** Prove that `D |-> ?D` is a functor by defining for each `f : D -> E` a
    mapping
> `?f : ?D -> ?E` by the formula
> `?_{i<n} X_i ?f ?_{j<m} Y` iff forall i<n exists j<m. X_i f Y`.
> Be sure to check that `?f` is approximable and that `?` preserves identity maps and
    composition.
> If `f` is computable, is `?f`? Is there a combinator `fun f. ?f`? What is `?f({x, y}) = ??`

## The mapping `?f`

Scott's formula refers to a *representation* `A = ?_{i<n} X_i`, which is not unique. We give
the
**representation-independent** relation

`(?f).rel A B := A in ?D /\ B in ?E /\ forall X in A, exists Y in B, X f Y`
(`PFmap`),

and prove it agrees with Scott's display on any generators (`PFmap_rel_fin`): for finite lists
`L_1 subseq ?`, `L_2 subseq ?`,

`(?f).rel (?_{X in L_1} X) (?_{Y in L_2} Y) <-> forall X in L_1, exists Y in L_2, X f
Y`.

The two readings coincide because every member `X` in `A` lies below a generator `X_i` and `f`
is
monotone (`mono`), and conversely each generator is itself a member. Approximability (`PFmap`)
uses:
`master_rel` from `f.master_rel`; `inter_right` from `f.inter_right` together with the fact
that the
power domain is *downward closed* (`PDmem_down`) so the witness `Y I Y''` lands back in `B I
B''`;
`mono` is immediate (the body only quantifies over set membership).

## Functoriality

* `PFmap_idMap` -- `?(I_D) = I_{?D}` (the body `forall X in A, exists Y in B, X subseq
Y` collapses to `A subseq B` by
downward closure).
* `PFmap_comp` -- `?(g comp f) = ?g comp ?f`. The non-trivial direction builds the
intermediate
`?E`-neighbourhood `B = ?_{Y in M} Y` from a list `M` of witnesses gathered along the
generators of
`A` by a **choice-free** list recursion (`comp_witness`: `obtain`-ing each existential
witness in a
`Prop` goal needs no choice).

## Discussion (Scott's three questions)

* **If `f` is computable, is `?f`? ** *Yes* (`PFmap_isComputable` / `PFmap_isComputable_Ypd`).
Over the
canonical presentations of Proposition 7.10 (`PDPresentation`, codes = finite lists of `?-
indices`),
the relation reduces (`PFmap_rel_Ypd_iff`) to
`forall a in dl c, exists b in dl d, X? f Y_b`, a bounded `forall`-`exists` over the
r.e. relation `X? f Y_b`; r.e.-ness
is preserved by bounded `exists` (`bExists_decodeList_re`) and bounded `forall` with a
parameter
(`REPred.forall_mem_decodeList_2`). So `?f` is computable whenever `f` is.

```

```

* **Is there a combinator `fun f. ?f`? ** *Yes* -- and built in full: **`PFmapComb`** is a
  genuine
  `ApproximableMap (funSpace V W) (funSpace V.PowerDomain W.PowerDomain)`, i.e. an element of
  `(D -> E) -> (D -> ?E)` in Scott's sense (Theorem 3.10's `funSpace`). Its relation is
  the flat
  Smyth-style lift `(?, ?) |-> mem ? /\ mem ? /\ forall f in ?, ?f in ?` (exactly
  the recipe of Exercise 7.16's
  `curryComb`/Exercise 7.21's `papplyEval`, one level up). **Faithfulness**
  (`PFmapComb`toElementMap`) confirms it *really is* `fun f. ?f`: under the function-space
  correspondence `funSpaceEquiv` (Thm 3.10, `toFilter`/`toApproxMap`),
  `(PFmapComb).toElementMap (toFilter f) = toFilter (PFmap f)` for **every** `f : D -> E` --
  not just
  finite/principal ones. The non-trivial direction gathers, for an arbitrary target
  neighbourhood
  `? = ?? [A?, B?]', a single finite witness list `M` of `D x E`-pairs (`
  exists_stepFun_forall_PFmap_rel`,
  built by the choice-free two-level list recursion `gather_witnesses` + outer induction) such
  that
  *every* `g` agreeing with `f` on `M` again has `?g in ?` -- precisely the continuity of `f
  |-> ?f`
  unbound to finite data, in the same spirit as Theorem 7.4 / Exercise 7.21's combinators.
* **What is `?f({x, y})`? ** The finite element `{x, y} in |?D|` is the principal element of
  the
  generator `X U X'` (with `x = X`, `y = X'`); by `PFmap_rel_fin` its image under `?f` is
  generated by `(f x) U (f x')`, i.e. `?f({x, y}) = {f x, f x'}` -- `?f` is the *image*
  operation.

```

```

Axiom audit: every declaration carries `Classical.choice`, but only at the `Prop` level and
  only
  *inherited* from the power domain itself: `??`'s closure under intersection (Proposition 7.10's
  `PDmem_upSet_inter`) decides neighbourhood membership in an arbitrary system by `by_cases`,
  which is
  genuinely undecidable at this generality. The new content of this file (the relation `PFmap`,
  the
  display formula, both functor laws, and the r.e. reductions) adds **no further** use of choice;
  the
  closure layer of `Recursive.lean` is choice-free, so `PFmap_isComputable` add only the axioms
  of the
  input `hf` on top of the power-domain's inherited `Classical.choice`.

# Exercise 7.20 (Scott 1981, PRG-19, S7) -- the combinator `union : ?(D) -> D`

> **EXERCISE 7.20.** Show that there is a combinator `union : ?(D) -> D` where for suitable
> neighbourhoods
> `?_{i<n} (?_{j<m_i} X_{ij}) union ?_{k<q} Y_k` iff forall i<n forall j<m_i exists k<q
> . X_{ij} subseq Y_k`.
> Is `union` computable if `D` is effectively given? What is `union({x}, {y, z})` = ??
> Are `?(D)` and `D` generally isomorphic??

`union` is the multiplication of the Smyth power-domain monad (`?`, Definition 7.9): it

```

```

*flattens* a "set of sets of elements" into a "set of elements". Its companion unit is the
  singleton
` : D -> ?D`; together they make `?` a monad, and `union` is the level-collapsing `? : ??D
  -> ?D`.

## The combinator (`unionMap`)

A member `S` in `A` of a `??D`-neighbourhood `A` is itself a `?D`-neighbourhood; a member `X`
  in `S` is a
`D`-neighbourhood. We give the representation-independent relation

`(union).rel A B := A in ??D /\ B in ?D /\ forall S in A, forall X in S, exists
  Y in B, X subseq Y` (`unionMap`),

and prove it agrees with Scott's display on generators (`unionMap_rel_fin`): for nested finite
  lists
`LS : List (List ?)`, `LY : List ?`,

`(union).rel (?_{l in LS} _{?D} (?_{X in l} X)) (?_{Y in LY} Y) <-> forall l in LS,
  forall X in l, exists Y in LY, X subseq Y`,

exactly Scott's `forall i<n forall j<m_i exists k<q. X_{ij} subseq Y_k`. The two
  readings coincide by downward closure
(`PDmem_down`, at both levels) plus `subseq`-monotonicity, mirroring Exercise 7.19's `
  PFmap_rel_fin` one
level deeper. Approximability: `master_rel` sends everything below `Delta`; `inter_right`
  narrows the
target witness to `Y I Y` (a `D`-neighbourhood because `X subseq Y I Y` witnesses
  consistency, landing
back in `B I B` by `PDmem_down`); `mono` is immediate.

## Discussion (Scott's three questions)

* Is `union` computable when `D` is effectively given? *Yes -- in fact recursively
  decidable.*
Over the canonical presentations of Proposition 7.10 (`??`-codes = finite lists of indices),
  the
relation reduces (`unionMap_rel_Ypd_iff`) to the nested bounded quantifier
`forall c in dl C, forall a in dl c, exists b in dl d, X? subseq X_b`, which is
  recursively decidable (two
`RecDecidable.bForallList` over `RecDecidable.bExistsList` of `P.incl_computable`, exactly
  the shape
of `subCode_computable`), hence r.e. (`unionMap_isComputable`). The double presentation of
  `??D`
uses, as its inner consistency decider, the constant `{}`-decider (the empty union `code 0`
  is below
every `D`-neighbourhood), just as in Proposition 7.10.
* What is `union({{x}, {y, z}})`? The finite element `{x}, {y, z}` in `|??D|` is the
  principal
element of the generator `_{?D}{x} U _{?D}{y,z}` (with `{x}, {y,z}` in `|?D|`); by `
  unionMap_rel_fin`
its image is generated by `x U y U z`, i.e. `union({{x}, {y, z}}) = {x, y, z}` -- the
  set-theoretic union of the member-sets. `union` is the flattening operation.
* Are `??D` and `?D` generally isomorphic? *No.* `?` is not idempotent. `union` and the
  unit
` : ?D -> ??D` are not mutually inverse: `union` collapses nesting, identifying distinct
  elements
of `|??D|` -- e.g. (whenever `|D|` has two incomparable finite elements `x, y`) the nested
  elements
`{{x}, {y}}` and `{x, y}` of `|??D|` both flatten to the same `{x, y}` in `|?D|`, so `union`
  is not
injective on elements and therefore is no isomorphism. (`??D == ?D` does hold in degenerate
  cases,

```

e.g. when $|D|$ is a single point.)

Axiom audit

Mirroring Exercise 7.19: every declaration here carries `Classical.choice`, but only at the `Prop` level and only **inherited** from the power domain itself -- `??`'s closure under intersection (Proposition 7.10's `PDmem_upSet_inter`, used to build `V.PowerDomain` and again `V.PowerDomain` `PowerDomain`) decides neighbourhood membership in an arbitrary system by `by_cases`. The new content of this file (the relation `unionMap`, the displayed formula, and the recursive reductions) adds ***no further*** use of choice; the recursion layer of `Recursive.lean` is choice-free.

Exercise 7.21 (Scott 1981, PRG-19, S7) -- combinators on the power domain

```
> **EXERCISE 7.21.** Is there a non-trivial combinator of type `(D -> E) -> (?D -> ?E)`?
> Are there in general any isomorphisms between the systems `(D -> ?E)`, `(D x E)`, `(D x ?E)`?
> Is there a non-trivial combinator of type `(D x E) x (E x F) -> (D x F)`?
> Is there any connection between `N` and `PN`?
```

This file answers the **first** (headline) question with a full construction and discusses the rest.

The headline combinator `papply : (?D -> E) -> (?D -> ?E)`

A `(D -> E)`-neighbourhood `A` is a finite union of down-sets of *function-space* neighbourhoods; a

`D`-neighbourhood `A` is a finite union of down-sets of `D`-neighbourhoods. The natural -- and non-trivial -- combinator "applies a set of functions to a set of arguments" by collecting all the applications. It is exactly the **Smyth power-domain lift of evaluation** (Theorem 3.11's `eval : (D -> E) x D -> E`):

```
`papplyEval.rel ? A B := ? in ?(D -> E) /\ A in ?D /\ B in ?E /\ forall G in
?, forall X in A, exists Y in B, G, X eval Y,
```

the two-variable analogue of Exercise 7.19's `f` (one level: `forall X in A, exists Y in B, X f Y`) and of

Exercise 7.20's `union` (the nested `forall forall exists`). Packaged as the two-variable map `papplyEval`, made a

map out of the product `papplyB = ofMap\_2 papplyEval : (?D -> E) x ?D -> ?E`, and finally **curried**

(Theorem 3.12) to the *exact* type Scott asks for:

```
`papply = curry papplyB : (?D -> E) -> (?D -> ?E).
```

It is **non-trivial**: `papplyEval\_step\_witness` exhibits, for any neighbourhoods `X\_0` in `D`, `Y\_0` in `E`,

the relation `[X\_0, Y\_0] papply X\_0 |-> Y\_0` -- the set of functions sending (at least) `X\_0` to `Y\_0`,

applied to (at least) `X\_0`, yields (at least) `Y\_0`. (Compare Exercise 7.19's image action `f({x,y}) = {f x, f y}` -- here the function is itself drawn from a power domain.)

Computability (the implicit "if `D`, `E` effectively given" half)

Yes, `papply` is computable whenever `eval` is. Over the canonical presentations of Proposition

7.10 (???-codes = finite lists of indices), the relation reduces (`papplyEval\_rel\_Ypd\_iff`) to the

triply-nested bounded quantifier

```
`forall g in dl ?c, forall x in dl Ac, exists y in dl Bc, eval (Pf.X g) (P.X x) (Q.X y)`,
```

recursively enumerable (`papplyEval\_isComputable`) because each layer preserves r.e.-ness: bounded

`exists` (`bExists\_decodeList\_re`, Ex 7.19) and parameterised bounded `forall`

(`REPred.forall\_mem\_decodeList\_2`), assembled by the helper `re\_forallG\_forallX\_existsY`. The

```

base
predicate ``eval` is r.e. on codes" is precisely Theorem 7.5's `evalMap_isComputable` (
  transported to
the ternary relation through the function-space presentation `funPresentation`), so we take it
  as the
hypothesis `heval` -- exactly as Exercise 7.19/7.20 take the component presentations as inputs.

## The other three questions (discussion)

* **Isomorphisms among `(D -> ?E)`, `?(D x E)`, `?D x ?E`** *Not in general.* There are
  always
  canonical *maps* -- e.g. `\mapsto `?(D x E)`-style -- but
  none is an
  isomorphism for non-degenerate `D, E`. The Smyth power domain does **not** distribute over
  the
  product: `?(D x E)` records *correlated* sets of pairs `{(d,e)}`, whereas `?D x ?E` only
  records the
  two *marginals*; the map `?(D x E) -> ?D x ?E` forgets the correlation and is not
  injective on
  elements (e.g. `{(d_1,e_1),(d_2,e_2)}` and `{(d_1,e_2),(d_2,e_1)}` have the same marginals).
  Likewise
  `(D -> ?E)` (one set of outputs *per input*) carries strictly more information than a
  single
  `?(D x E)`. So these are related by combinators, not isomorphisms, in general.
* **A combinator `?(D x E) x ?(E x F) -> ?(D x F)`** *Yes* -- **relational
  composition**, the Smyth
  lift of "compose the underlying relations": send sets `R`  $\subseteq$  `D x E`, `S`  $\subseteq$  `E x
  F` to
  `R ; S = {(d,f) | exists e, (d,e) in R /\ (e,f) in S}`. On neighbourhoods, `prodNbhd X
  Y` in `R`,
  `prodNbhd Y' Z` in `S` with `Y, Y'` consistent produce `prodNbhd X Z`; the middle witness `Y
  I Y'`
  is gathered exactly as Exercise 7.19's choice-free `comp_witness`. It is the same recipe as
  `papply` (a binary Smyth lift), so "yes, and computable", and is not pursued in code here.
* **Connection between `?N` and `PN`** Here `N` is the flat domain of naturals (Lecture VII's
  `? = N`)
  and `PN` is the powerset domain `?(Nat)` of Example 7.8. The Smyth power domain `?N` consists
  of the
  *finitely generated Smyth predicates* on `N`; its finite elements are finite sets of naturals
  (plus `False`), and the embedding "finite set  $\mapsto$  its set of members" realises `?N` as the
  sub-domain of
  `PN` of finitely generated elements -- `?N ? PN` (Proposition 7.12's singleton/union
  machinery),
  with `PN` the ideal completion. They are *not* isomorphic (`PN` has uncountable elements, `?N`
  has
  elements are the r.e./finite ones), but `?N` sits inside `PN` as its computable/finitary core
  .

## Axiom audit

As in Exercises 7.19/7.20, every declaration carries `Classical.choice`, but only at the `Prop`
  level
  and only *inherited* from the power domain itself (Proposition 7.10's `PDmem_upSet_inter`
  by_cases`,
  used to build `PowerDomain`). The new content here -- `papplyEval`, the displayed reduction,
  the r.e.
  helper, and the curried combinator -- adds **no further** use of choice; the recursion layer of
  `Recursive.lean` is choice-free.

# Exercise 7.22 (Scott 1981, PRG-19, S7) -- a domain over  $\{0,1\}^*$  by least fixed point

> **EXERCISE 7.22.** (For algebraists.) Let  $\Sigma = \{0,1\}^*$  be the free semigroup. A new
  domain is
> constructed by defining a family of sets by the least fixed point theorem as follows:
>
>  $S = \{\Sigma\} \cup \{\{\sigma\} \mid \sigma \in \Sigma\} \cup \{XY \mid X, Y \in S\} \cup \{X \mid Y \mid X, Y \in S \text{ and } X \mid Y \neq \{\}\}.$ 
>
> Here  $XY = \{\sigma\tau \mid \sigma \in X \text{ and } \tau \in Y\}.$ 
>
> Prove that  $S$  is an effectively given, positive neighbourhood system. (Hint: the sets in  $S$ 
  are
> each "regular events" in the terminology of automata theory, and we have a decision method
  for the
> set algebra of regular events.)
>
> Define multiplication on  $|S|$  by  $xy = \{Z \in S \mid \exists X \in x \exists Y \in y. XY \subseteq Z\},$  and show  $|S|$  becomes
> a semigroup with  $\Sigma$  embedded into  $|S|$  by the homomorphism  $\sigma \mapsto \{X \in S \mid \sigma \in X\}.$ 
>
> Investigate some *infinite words* in  $S$ , say those defined by least fixed points such as
>  $\sigma\text{-vec} = \sigma \sigma\text{-vec}$  and  $\sigma\text{-vec} = \sigma\text{-vec} \sigma.$  Are the equations  $\sigma\text{-vec} \sigma\text{-vec} = \sigma\text{-vec},$ 
   $\sigma\text{-vec} \sigma\text{-vec} \sigma\text{-vec} = \sigma\text{-vec},$ 
>  $\sigma\text{-vec} 1\text{-vec} \sigma\text{-vec} 1\text{-vec} = \sigma\text{-vec} 1\text{-vec},$  and  $01\text{-vec} 01\text{-vec} 01\text{-vec} 01\text{-vec} = 01\text{-vec} 01\text{-vec}$ 
  true?

This file formalises the **algebraic core** of the exercise, fully and choice-free:

* the least-fixed-point family  $S$  as an inductive predicate  $\text{In}S$  over tokens  $\Sigma = \{0,1\}^* = \text{List Bool};$ 
*  $S$  is a **positive neighbourhood system**  $S_{\text{sys}}$  (Definition 1.1 / Exercise 1.19), built
  choice-free

```

```

via `NeighborhoodSystem.ofPositive`;
* the **multiplication** `xy` on the domain `|S|` and the proof that it is **associative**, so
  `|S|`
  is a semigroup (`mulElem`, `mulElem_assoc`);
* the **embedding** `sigma |-> {X in S ? sigma in X}` of the free monoid into `|S|`,
  proved a semigroup
  **homomorphism** (`emb_mul`) and **injective** (`emb_injective`);
* Scott's **infinite words** `sigma-vec`, as genuine least fixed points `sigma-vec = sigma *
  sigma-vec` (Theorem 4.1) of
  `x |-> sigma*x` realised as an approximable self-map `prependMap sigma` on `|S|`, and **all
  four of Scott's
  equations**, proved unconditionally (`streamArrow_mul_self` and friends, **Exercise 7.221**).

## Effective givenness (mechanised elsewhere in the project)

Every member of `S` is a regular event (Scott's hint), and effective givenness is **fully
mechanised** (not a gap): `Exercise722Regular.lean` (regularity), `Exercise722Decide.lean` /
`Exercise722Cat.lean` / `Exercise722Equiv.lean` (explicit finite automata; emptiness and
  language
  equivalence deciders), `Recursive.lean` (the choice-free primitive-recursive `Nat.Primrec`
  mirrors),
  and `Exercise722Presentation.lean` (`Ssys_cons_computable`, `Ssys_interEq_computable`:
  Definition 7.1
  relations (ii) and (i) are recursively decidable). See `arxiv.md`, Exercise 7.22a-k (all Pass).

## Infinite words (Exercise 7.221)

Scott's last questions ask about *infinite words* in `S` and whether certain multiplicative
equations hold in `|S|`. We answer them **the way Scott poses the question**: `sigma-vec` is a
  genuine
**least fixed point in the domain `|S|`**, `sigma-vec = sigma * sigma-vec` (`streamArrow`, `
streamArrow_eq`), built with
  this project's existing Theorem 4.1 machinery -- the same construction as `Example44.lean`'s
  alternating sequence `a = 0(1a)` -- rather than a set-theoretic proxy. All four of Scott's
  equations
  then hold **unconditionally**, with no side-condition and no open question:
  `streamArrow_mul_self` (`sigma-vecsigma-vec = sigma-vec`), `streamArrow_mul_self_self` (`sigma-
  vecsigma-vecsigma-vec = sigma-vec`),
  `streamArrow_mul_self_append_true` (`sigma1-vec * sigma1-vec = sigma1-vec`), and `
streamArrow_containsZero_pow_four`
  (`01-vec01-vec01-vec01-vec = 01-vec01-vec`).

(An earlier pass answered the same questions via a *set-theoretic proxy* instead: `streamElem w
`,
  the filter `Z |-> InS Z /\ forall n, w? in Z`, conditional on the side-question `InS (
  powerLang w)` -- is the
  language `{w?}` itself a member of `S`? That side-question turned out to be a genuinely open
  combinatorics-on-words question (kept below, `streamElem`/`powerLang`, for reference), but it
  is
  **not** Scott's question -- it was an artefact of choosing that particular proxy, and `
streamArrow`
  above answers Scott's actual equations without ever needing it.)

Everything in this file depends only on `propext` / `Quot.sound` (no `Classical.choice`).

/-! ## Infinite words as genuine least fixed points (Exercise 7.221)

Scott's actual question defines `sigma-vec` as a least fixed point in the domain  $|S|^{**}$ :
  sigma-vec = sigma * sigma-vec`
(Theorem 4.1's construction, already built for exactly this purpose, e.g. `Example44.lean`'s
alternating sequence `a = 0(1a)`). We realise `x |> sigma * x` as an approximable self-map on
`Ssys`
(`prependMap`, generalising `Example44.lean`'s `consMap` from a single bit to a whole word),
and
take `sigma-vec := (prependMap sigma).fixElement`. This gives Scott's equation unconditionally
  * -- no side
condition on `InS (powerLang sigma)` is needed, and (Theorem 4.1's construction being choice-
free) no
`Classical.choice` is pulled in either. -/

/--  $x \mapsto \sigma * x$ , realised as an approximable self-map on  $|S|^{**}$ . Mirrors `Example44.
lean`'s

# Exercise 7.22 (Scott 1981, PRG-19, S7) -- the regular-event layer

This file develops the "regular events" hint of Exercise 7.22 toward *effective givenness*
of the
neighbourhood system `Ssys` of `Exercise722.lean`. Scott's hint:

> the sets in `S` are each "regular events" in the terminology of automata theory, and we have
  a
> decision method for the set algebra of regular events.

## What is mechanised here (green, choice-free)

We make the "regular event" content precise by giving `S` a finite **syntax** and a denotation,
and
proving the syntax exactly captures `S`:

* `SEExpr` -- the syntax of `S`--terms: `Sigma` (`sigma`), a singleton `{sigma}` (`single sigma`)
  , concatenation
  `X*Y` (`cat`), and intersection `X I Y` (`cap`). This is a *fragment* of regular
  expressions
  (closed under `*` and `I`, with the universal language `Sigma`), with **no** union,
  complement, or
  Kleene star -- exactly Scott's four generators.
* `denote : SEExpr -> Set (List Bool)` -- the language denoted by a term.
* **Decidable membership** `decide (w in denote e)` via a `Bool` matcher `matchesB` with
  `matchesB_iff`, giving `DecidablePred (* in denote e)` (choice-free). This is the
  computational core
  of "regular event": *membership of a word is decidable*.
* **Soundness/completeness**: `InS (denote e)` whenever `denote e` is non-empty
  (`InS_denote_of_nonempty`), and every member of `S` is a denotation (`InS_exists_denote`).
  Hence the
  exact characterization `InS X <-> exists e, denote e = X /\ X.Nonempty` (`
  inS_iff_exists_denote`).
* `SEExpr` is countable (`Encodable SEExpr`), so `S` is at most countable (Scott's standing
  finiteness).

## What remains for full effective givenness (Definition 7.1) -- documented, not mechanised

Building a `ComputablePresentation`/`ScottPresentation Ssys` (Definition 7.1) requires Scott's
two
relations to be **recursively decidable**, i.e. computed by genuine *primitive-recursive*
functions
(`Domain.Recursive.RecDecidable = exists f, Nat.Primrec f /\ ...`); classical decidability
does **not**
suffice. Over the syntax codes the two relations are:
```

```

* (ii) consistency `exists k. X_k subseq X_n I X?` ? (by positivity, Exercise 1.19 /
  `Ssys_isPositive`)
  non-emptiness of `denote e_n I denote e?` = non-emptiness of `denote (cap e_n e?)`;
* (i) `X_n I X? = X_k` is language equivalence `denote (cap e_n e?) = denote e_k`.

Both are decidable for regular events, but the decision procedures are automata-complete:

* Emptiness of an intersection genuinely needs the product-automaton reachability argument (
  there is
  no structural recursion for `I`-emptiness: e.g. `Sigma{0}Sigma I Sigma{1}Sigma` is non-
  empty while `{00} I {11}`
  is empty), and a bounded-search emptiness test needs a proven state/length bound from a DFA
  .
* Equivalence is not reducible to intersection-emptiness inside this class, because the
  class is
  not closed under complement/difference (`L_1 subseq L_2 ? L_1 \ L_2 = {}` needs `\`).
  It requires a
  regular-language equivalence procedure (minimal DFAs / Myhill-Nerode, cf. `Example62Regular.
  lean`).

Mechanising those choice-free in `Recursive.lean` (a primitive-recursive subset construction +
reachability + a pumping/length bound, then `matchesB` over a bounded word set) is a separate,
large
undertaking. Everything in this file is `subseq {propext, Quot.sound}` (no `Classical.
choice`).

/-! ## Countability of `S`

`SExpr` is built from `List Bool` by finitely many constructors, hence countable; so `S`, being
the
range of `denote` (restricted to non-empty denotations), is at most countable -- Scott's
standing
"at most a countable infinity of neighbourhoods" (Definition 7.1). We record the range
presentation;
the countability of `SExpr` itself is immediate (a finitely-branching inductive over the
countable
`List Bool`) and not needed below. -/

/-- The set of `S`-languages is the range of `denote` (on `SExpr`), hence the image of a
countable
type: `S = denote '' {e | (denote e).Nonempty}`. This realises the enumeration backbone of an
effective presentation; what it does *not* yet supply is the recursive *decidability* of Scott'
s two
index relations (see the module docstring). -/
theorem inS_eq_range_denote : {X | InS X} = denote '' {e | (denote e).Nonempty} := by
  ext X

  * rintro <e, hne, rfl>
    exact InS_denote_of_nonempty hne

/-! ## Reducing Definition 7.1's two relations to language equivalence on `SExpr`

```

The enumeration of $\mathcal{S}$ is (essentially) $n \mapsto \text{denote}(\text{decode } n)$ for codes $\text{decode } n : \text{SEExpr}$. Over such codes, Scott's two recursive-decidability obligations of Definition 7.1 become:

```
* ** (ii) consistency  $\exists k. X_k \subseteq X_n \wedge X_n \neq \emptyset$  (positivity)  $\neg (\text{denote } e_n \wedge \text{denote } e_n = \emptyset)$ .
* ** (i)  $X_n \wedge X_n = \emptyset \iff \text{denote } (\cap e_n) = \text{denote } e_n$ .
```

We show **both** are instances of *deciding language equivalence* of two SEExpr 's -- and that emptiness alone is therefore **not** enough (relation (i) needs the full equivalence test). -/

```
/-- The empty language is denotable in the fragment (it is not a member of  $\mathcal{S}$ , which is positive):  $\{0\} \wedge \{1\} = \emptyset$ . This is the canonical " $\{\}$ " expression used to phrase emptiness as an equivalence query. -/
def emptyExpr : SEExpr := .cap (.single [false]) (.single [true])
```

```

/-! ## Why an emptiness decider is **not** enough (the concrete obstruction)

Relation (i) is genuine regular-language **equivalence**, which is strictly stronger than fragment-emptiness, because the fragment is **not** closed under complement / set-difference ($L_1 \subseteq L_2 \iff L_1 \setminus L_2 = \emptyset$ needs $\neg$). The following exhibit the obstruction concretely. -/

```
/-- "Contains a 0" as a fragment expression:  $\Sigma * \{0\} * \Sigma$ . -/
def containsZero : SEExpr := .cat .sigma (.cat (.single [false]) .sigma)
```

```
/--  $\text{denote } .\text{sigma} = \Sigma$  contains every word. -/
theorem mem_denote_sigma (w : List Bool) : w in denote .sigma := Set.mem_univ w
```

```
/--  $\text{denote}$  is far from injective:  $\Sigma * \Sigma = \Sigma$ . A nontrivial language identity (with distinct syntax), so relation (i)  $X_n \wedge X_n = X_k$  is not syntactic equality of codes -- it is genuine regular-language equivalence, the whole difficulty of the exercise. -/
theorem denote_catSigmaSigma : denote (.cat .sigma .sigma) = denote .sigma := by
```

```

# Exercise 7.22 -- toward effective givenness: explicit `Fintype` DFAs (WIP)

This is work in progress toward a choice-free decision procedure for the two Definition-7.1
relations of `Ssys` (`Exercise722.lean`), reduced in `Exercise722Regular.lean` to language
equivalence on `SEExpr`. The plan (Route A): give every `SEExpr` an explicit deterministic
    finite
automaton with a genuine `Fintype` state type, so that emptiness/equivalence become 
    structural
finite searches (no Brzozowski-finiteness/ACI theorem needed).

mathlib supplies the closure operations we need for free:
* `DFA.inter` (`accepts_inter : (M_1.inter M_2).accepts = M_1.accepts sqcap M_2.accepts`) --
    handles `cap`;
* `DFA.compl` (`accepts_compl`) + `inter` + emptiness -- handles equivalence (`A = B <-> A ?
    B = {}`).
```

What mathlib does **not** supply, and what remains the crux (designated for a high-compute session):

```

* a language-concatenation automaton (`cat`): no NFA/?NFA concatenation exists in mathlib,
    so it
    must be built (?NFA with ?-links from `a`'s accept states to `b`'s start) and proved correct
    (`accepts = denote a * denote b`) via `?NFA.IsPath`/`isPath_append`;

```

```

* a `Finset`-based subset construction (mathlib's `NFA.n` determinizes to `Set sigma`, which
  lacks
  `DecidableEq`), needed so the final emptiness/equivalence search is decidable data;
* the bridge from the resulting `Decidable` search to the project's `RecDecidable` (`Nat.
  Primrec`).

**This file (Medium pass) provides the leaf automata, proven correct, and the framework.** The
`cat`
construction and the decision bridge are the remaining (high-compute) work.

# Exercise 7.22 -- the concatenation automaton (the crux mathlib lacks)

mathlib provides NFA/?NFA/DFA with intersection (`DFA.inter`) and complement, but no
language-concatenation automaton**. This file builds one and proves it correct, choice-free.

Given two NFAs `M_1`, `M_2` we form an `?NFA` `catEps M_1 M_2` on the sum state type `sigma_1 ?
  sigma_2`:
copies of `M_1` (on the `inl` side) and `M_2` (on the `inr` side), with an ??-edge from every
accept state of `M_1` to every start state of `M_2`**. The headline result is

  `(catEps M_1 M_2).accepts = M_1.accepts * M_2.accepts`   (`catEps_accepts`)

proved via the closed form (`catEps_eval`)

  `(catEps M_1 M_2).eval x = inl '' (M_1.eval x)  U  inr '' { t | exists u v, x = u ++ v /\
    u in M_1.accepts /\
                                     t in M_2.eval v }`

i.e. the reachable `inr`-states after reading `x` are exactly the `M_2`-states reachable from
some
split `x = u ++ v` with the `M_1`-prefix `u` accepted. The `Sum` state type stays `Fintype`, so
this
plugs into the `Fintype`-DFA/NFA decision route (`Exercise722DFA.lean`).

# Exercise 7.22 -- every fragment expression has a `Fintype` automaton (`denote e = accepts`)

Assembles the leaf automata (`Exercise722DFA.lean`) and the concatenation automaton
(`Exercise722Cat.lean`) into a single uniform recogniser

`toNFA : (e : SExpr) -> NFA Bool (autState e)` with `toNFA_accepts : (toNFA e).
accepts = denote e`

where the state type `autState e` is a `Fintype` (built from `Unit`, `Option (Fin _)`, `x`,
`?`).
This is the constructive, **choice-free** realisation of Scott's "the sets in `S` are regular
events":
every fragment language is the accepted language of an explicit finite automaton. It is the
platform
for the emptiness/equivalence decision procedure (and hence Definition 7.1 effective givenness)
.

The missing combinator beyond the leaves+`cat` is intersection, handled here by the standard
product
construction `NFAinter` (mathlib has `DFA.inter` but no `NFA` intersection).

/-! ## Emptiness reduces to reachability of an accept state

Since the state space is a `Fintype`, this reduces Definition 7.1's relation (ii) --
consistency,
which by positivity of `Ssys` (`Exercise722.lean`) is exactly `I`-non-emptiness -- to a **
finite**
reachability question. The two clean routes to a primitive-recursive decider from here are
flagged in
the module docstring of `Exercise722DFA.lean`. -/

/-! ## Consistency decider (Session C6) -- Definition 7.1 relation (ii)

For `X, Y in S`, Scott's consistency `exists Z in S, Z subseq X I Y` is equivalent
to `(X I Y).Nonempty`
by positivity (`Ssys_isPositive`). On syntax, this is non-emptiness of `denote (cap a b)`. -/

/-- Decides relation (ii) on a pair of expressions: `true` iff `denote a I denote b` is non-
  empty. -/
def consistentB (a b : SExpr) : Bool := !decideEmptyB (.cap a b)

/-- **Definition 7.1 (ii) for encoded neighbourhoods:** when `denote a`, `denote b` in `S`,
`consistentB` agrees with membership of the intersection in `S`. -/
theorem consistentB_iff_Ssys (a b : SExpr) (ha : InS (denote a)) (hb : InS (denote b)) :
  consistentB a b = true <-> InS (denote a I denote b) := by
  rw [ <- denote_cap, consistentB_iff]
  exact Iff.symm (Ssys_isPositive (Ssys_mem.mpr ha) (Ssys_mem.mpr hb))

```

```

/-! ## Relation (i) `interEq` -- what `decideEmptyB` / `consistentB` do not decide (Session C7a)

**Definition 7.1 (i)** on an encoded presentation is the ternary relation
`X_n I X? = X?`. On `SEExpr` syntax this is exactly regular-language equivalence
(`interEq_iff` in `Exercise722Regular.lean`):

  `denote a I denote b = denote k <-> denote (cap a b) = denote k`.

Relation (ii) consistency is now mechanised (`consistentB` / `decideEmptyB` on `cap a b`).
Relation (i) is strictly harder: it asks whether two different syntactic caps denote the
same language, not merely whether their intersection is empty.

**Why emptiness alone is insufficient.** The fragment is not closed under complement or set-
difference
(`L_1 subseq L_2 <-> L_1 \ L_2 = {}` needs ``). The concrete obstruction is `
sigma_ne_containsZero`:
`denote .sigma != denote containsZero` (witness `[true]` in `Sigma` but `[true]` not in `Sigma
*{0}*Sigma`), yet no
fragment-emptiness query on `cap`/`cat`/`single`/`sigma` alone exposes this inequality --
detecting
`Sigma \ "contains 0"` needs the complement language `{1}*`, which is not expressible in
the
fragment. Hence `decideEmptyB` and `consistentB` cannot decide (i).

**What a full (i) decider would need (Session C7b, DEFER).** Language equivalence
`denote e_1 = denote e_2` reduces to emptiness of the symmetric difference, hence to deciding
`(e_1 I e_2?)` and `(e_2 I e_1?)` -- i.e. complement (`complDFA` exists) wired into a
uniform
`toDFA` / product construction, or an alternative such as Myhill-Nerode bisimulation on the
`autState` types. Until C7b lands, `Ssys_partially_effectively_given` will carry (ii) only. -/

# Exercise 7.22 -- bounded word enumeration for emptiness search

Lists every `List Bool` of length at most `n` (`wordsUpTo n`), and provides `anyMatchesB` to
test
whether any word in a finite list is accepted by the `matchesB` matcher. The characterisation
`mem_wordsUpTo` is the length bound used later for pumping-based short-word search (Session C4)
.

# Exercise 7.22k -- language equivalence via a `Finset`-valued subset construction (Session C7b  
)
```

```
`toNFA e : NFA Bool (autState e)` is genuinely nondeterministic once `.cat` is involved (the  
concatenation automaton's ?-closure fans a single state out to several live states), so  
deciding  
`denote e_1 = denote e_2` cannot be reduced to a simple bounded search over `matchesB` alone:  
"e_2 rejects w" is a *universal* statement over e_2's nondeterministic paths, and  
universal  
statements over NFA paths don't pump the way existential ones do (`exists_accepted_word_short`)  
.
```

```
The fix is a **choice-free `Finset`-valued subset-construction simulation** of `toNFA e`: track  
the  
*entire* set of live NFA states as a `Finset (autState e)` (decidable, since `autState e`  
already  
carries `Fintype`/`DecidableEq`, `Exercise722Decide.lean`), evolving **deterministically**.  
Once  
both `e_1`'s and `e_2`'s live-state-sets are tracked simultaneously (as one `Finset`-pair state  
, the  
question "is there a word `e_1` accepts but `e_2` rejects" becomes an ordinary NFA-emptiness  
question  
on a *deterministic* (singleton-step) NFA, to which `exists_accepted_word_short` applies  
directly.

# Exercise 7.22 -- computable presentation backbone (`SsysX`)

Enumeration `n |-> SsysX n` for Scott's positive neighbourhood system `Ssys` (`Exercise722.lean`),
toward Definition 7.1 effective givenness. Indices decode to `SEExpr` codes; non-empty
denotations
are listed, while junk / empty-syntax indices map to the master neighbourhood `Sigma` so every
index
still names a member of `S` (`SsysX_mem`). Surjectivity onto `S` uses
`inS_iff_exists_denote` (`Exercise722Regular.lean`).

Sessions C9-C10 will add `RecDecidable_2` consistency and the `ComputablePresentation`
structure;
relation (i) `interEq` remains deferred (see `Exercise722Decide.lean`, Session C7a).

/-! ## Definition 7.1 (ii) -- recursively decidable consistency (Session C9)

Scott's consistency `exists k, X_k subseq X_n I X_m` on a positive system is equivalent
to
`(X_n I X_m).Nonempty` (`Ssys_isPositive`). On the `SsysX` enumeration, inactive indices
(decode failure / empty denotation -> `SsysX = Sigma`) make consistency automatic; active-
active
pairs reduce to `consistentB` on decoded expressions. -/

/-- Inactive index: decode fails or denotes the empty language (mapped to `Sigma` in `SsysX`).

/-! ### Session C9 -- `RecDecidable_2` (primitive-recursive bridge)

The mathematics is finished (`ssys_cons_char_iff`). The generic packaging lemma is
`RecDecidable_2.of_paired_zero_one_char` in `Recursive.lean`: once a `{0,1}`-valued
characteristic is
`Nat.Primrec`, `RecDecidable_2` follows immediately.

**Numeric characteristic** for the existing Bool decider (no new algorithm).

Unfolding `ssys_cons_char_iff` (which chains through `ssys_cons_iff` / `consistentB_iff`) can
exceed
the default 200000 heartbeat budget; raise the limit for this section only. -/

set_option maxHeartbeats 500000

/-! ### Session C9b7 -- `ssysActiveChar`, `ssysConsistentBChar`

`Recursive.lean` cannot import this file (it would cycle: `Presentation -> Definition71 ->
Recursive`), so its C9b5/C9b6 Godel mirror (`c9b5_sexprGodelEncode`/`c9b5_sexprDepth`) is a
self-contained *structural* copy of `SEExpr.encode`/`sexprDepth` above, not literally the same
function. The bridge equalities below (provable here, downstream, where both sides are visible)
let every C9b5/C9b6 correctness theorem be re-applied against the *real* `SEExpr.encode`/
`sexprDepth`/`denote`, without re-deriving any of their induction. -/

/-! ### Session C7b -- `ssysInterEqChar` (Exercise 7.22k)

Definition 7.1 relation (i) -- `SsysX n I SsysX m = SsysX k` -- via the `Exercise722Equiv.
  lean` /
`Recursive.lean` language-equivalence decider `interEqChar`. `safeDecodeActive` already gives a
uniform canonical `SEExpr` representative for every index (junk/inactive  $\mapsto$   $\texttt{.sigma}$ ,
`SsysX_eq_denote_safe`), so unlike `ssysConsistentBChar` (where inactive indices are trivially
*
consistent with anything, since  $\Sigma$  is the top element) there is no active/inactive case
split
here: equality is genuinely about the canonical representative in every case. -/

/-- The Gödel code of `safeDecodeActive n` (`ssysCanonicalCode_eq`): `n`'s own decoded code if
active, else the code of  $\texttt{.sigma}$  (matching `safeDecodeActive`'s junk fallback). -/

/-! ### Session C10 -- Definition 7.1 packaging for `Ssys` (Exercise 7.22j)

**Historical note (superseded by C7b / 7.22k, kept for the record).** At the time this session
ran,
relation (i) -- `X_n I X? = X_k`, i.e. whether two *different* syntactic caps denote the *
same*
language -- was open: strictly harder than emptiness/consistency, since the fragment
`{sigma, single, cat, cap}` is not closed under complement, so `consistentB`/`decideNonemptyB`
(which only ever test emptiness) cannot expose language inequality (concrete obstruction:
`sigma_ne_containsZero`, see `Exercise722Decide.lean`). So `Ssys` got a **partial**
presentation
carrying only what was proved then: the enumeration onto `S` (`SsysX`/`SsysX_mem`/`SsysX_surj`)
plus relation (ii) (`Ssys_cons_computable`).

**Session C7b since closed relation (i)** (`Ssys_interEq_computable`, below) via a choice-free
`Finset`-subset-construction automaton simulation (`Exercise722Equiv.lean`) -- so `Ssys` now
satisfies **all of Definition 7.1 exactly as Scott states it** (enumeration, plus both
relations
recursively decidable), between `SsysPres`/`Ssys_partially_effectively_given` here and
`Ssys_interEq_computable` in the C7b section. What is *not* provided is an instance of this
codebase's stronger `ComputablePresentation` (`Definition71.lean`) -- used throughout the rest
of
Lecture VII's formalisation (Theorem 7.4-7.6, Exercise 7.13-7.18, Proposition 7.7/7.10) --
which
additionally carries a primitive-recursive intersection witness `inter`/`inter_primrec`/
`inter_spec` and a `masterIdx`. Those two fields are not part of Definition 7.1's text and are
not
asked for by Exercise 7.22; completing them would be mechanical (7.22k's `ssysCanonicalCode`/
`capCode` already compute the right index) and is worth doing only if a later exercise wants to
feed `Ssys` into that shared apparatus. -/

/-- Definition 7.1 restricted to relation (ii) only (no `interEq_computable`, unlike
`ComputablePresentation`/`ScottPresentation` in `Definition71.lean`/`Exercise715.lean`, whose
pattern this mirrors). -/
structure ConsistencyPresentation (V : NeighborhoodSystem a) where
  /-- The enumeration `? = {X_n ? n in Nat}`. -/
  X : Nat -> Set a
  /-- Every `X_n` is a neighbourhood. -/
  mem_X : forall n, V.mem (X n)
  /-- The enumeration is onto `?`. -/
  surj : forall {Y : Set a}, V.mem Y -> exists n, X n = Y
  /-- **7.1(ii)** -- consistency `exists k. X_k subseq X_n I X?` is recursively
  decidable in `n, m`. -/
  cons_computable : RecDecidable_2 (fun n m => exists k, X k subseq X n I X m)

/-- A neighbourhood system is *partially* effectively given when it admits a presentation
carrying relation (ii) (but not necessarily (i)). Named at top level (not `NeighborhoodSystem
....`)
since `Definition71.lean` -- where `NeighborhoodSystem`/`ComputablePresentation` live -- is
outside
this session's edit scope; a future session may hoist `ConsistencyPresentation` there alongside

```

```

them for dot-notation parity with `IsEffectivelyGiven`. -/
def IsPartiallyEffectivelyGiven (V : NeighborhoodSystem a) : Prop :=
  Nonempty (ConsistencyPresentation V)

/-- The partial presentation of `Ssys`: enumeration `SsysX` onto `S`, consistency via
`Ssys_cons_computable`. -/
def SsysPres : ConsistencyPresentation Ssys where
  X := SsysX
  mem_X n := Ssys_mem.mpr (SsysX_mem n)
  surj hY := SsysX_surj (Ssys_mem.mp hY)
  cons_computable := Ssys_cons_computable

/-- Exercise 7.22j. `Ssys` -- Scott's positive system generated by singleton languages
under
concatenation and consistent intersection -- is partially effectively given: Definition 7.1
relation (ii) is recursively decidable (`Ssys_cons_computable`, closing C9 / **7.22i(b)**).

The name "partially" now undersells the full picture: relation (i) is also proven, separately
as `Ssys_interEq_computable` (Exercise 7.22k, `ConsistencyPresentation` was never extended with
an
`interEq_computable` field to absorb it). Together, `SsysPres` and `Ssys_interEq_computable`
show
`Ssys` satisfies Definition 7.1 **exactly as Scott states it** -- enumeration, plus both
relations
recursively decidable -- with nothing deferred. What remains unbuilt is only this codebase's
*stronger* `ComputablePresentation` (`Definition71.lean`), which the rest of Lecture VII's
formalisation relies on but which is not part of Definition 7.1's text; see the section
docstring
above. -/

# Exercise 7.23 (Scott 1981, PRG-19, S7) -- completing the discussion of `PN`

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.23.** Complete the discussion of `PN` of Example 7.8. Show that the combinators
> `fun` and `graph` of Exercise 5.14 are computable. Also do the same for `fun x,y. x I y`,
> `fun x,y. x U y`, and `fun x,y. x+y`, where for `x,y` in `PN` we define `x+y = {n+m ? n in x
and m in y}`.

```

```

> What are the computable elements of `PN`?

**The key structural fact.** Write `E n := Nat \ Example78.nbhd n = {k ? n.testBit k}` for the
finite
set Scott's `nbhd n` excludes. `Example78.nbhd n subseteq Example78.nbhd k <-> E k
  subseteq E n` (containment of
neighbourhoods *reverses* into containment of the excluded finite sets -- this is exactly
`ComputablePresentation.incl_computable`, already proven generically for any
`ComputablePresentation`, applied to `Example78.PNpres`). Every binary combinator `fun x,y. h(x
,y)`
this exercise asks about turns out to test a *containment of finite sets* `E k subseteq h(E n
, E m)`, which
is exactly `nbhd n subseteq nbhd k` (and/or `nbhd m subseteq nbhd k`) reindexed -- so **` I
  /\ U ` are computable
reusing `incl_computable` directly, with no new bitwise/primitive-recursive machinery**: ` I `
  is the
conjunction of two containments (`E? subseteq E_n I E? <-> E? subseteq E_n /\ E? subseteq E
  ?`), and ` U ` reduces to a single
containment against `myLor n m` (`E? subseteq E_n U E? <-> E? subseteq E_{myLor n m} <->
  nbhd(myLor n m) subseteq nbhd k`).

/-! ## `fun x,y. x+y` (Minkowski sum)

Scott's `x + y = {n + m ? n in x, m in y}`. Written on excluded sets, `E_n + E` (Minkowski
sum of two
*finite* sets) is again finite, and -- since `a + b` ranges over `E_n + E` exactly when `a`
ranges
over `E_n` and `b` over `E` -- `E_n + E = ? {a + E ? a in E_n}`, a union of shifted copies
of `E`, one
per set bit of `n`. This is computed by `plusIdx`, an iterative bitwise-OR fold (mirroring `
myLor`)
of `m <<< a` over the set bits `a` of `n`. -/

/-- Scott's `x + y = {n+m ? n in x, m in y}` (Minkowski sum) for `x, y subseq Nat`. -/

/-! ## What are the computable elements of `PN`?

Every element `x` of `PN` is a downward-directed filter of the cofinite neighbourhoods `nbhd n`
`.
Write `elemSet x := ? {E_n ? x.mem (nbhd n)}` for the (arbitrary) subset of `Nat` it "
positively
describes". Since `PN`'s neighbourhoods carry only *negative* information and any two are
consistent
(`PN_consistent`), each single fact `x.mem (nbhd n)` is *generated* by finitely many of the
positive
facts `k in elemSet x` (`k in E_n`) -- combine their witnesses with `myLor` (`
exists_combined_witness`) --
so `x.mem (nbhd n) <-> E_n subseqeq elemSet x` (`nbhd_mem_iff_subset_elemSet`). This
exhibits `PN` as

```

(isomorphic to) the classical powerset domain `(Set Nat, subseq)`, `x |-> elemSet x`, and
:

```
> **Theorem.** `x` is a computable element of `PN` iff `elemSet x` is a recursively enumerable
> subset of `Nat` (isComputableElement_iff_elemSet_re).
```

I.e. **the computable elements of `PN` are exactly the recursively enumerable sets** -- Scott's headline fact about the powerset domain. -/

```
/-- The subset of `Nat` "positively described" by a `PN`-element `x`: the union of the excluded
finite
sets of every neighbourhood it contains. -/

/#!/ ### `bitsCode`: a primitive-recursive coding of "the list of set bits below `N`"

Needed for the converse computability direction: to invoke the generic closure
`REPred.forall_mem_decodeList`, the bounded conjunction `forall k in E_n, k in A` must be
phrased over a
*coded* list (`decodeList`), built by primitive recursion -- not the plain `List.filter` form
`bitsList` above (which lives in `List Nat`, outside the `Nat.Primrec` universe). `bitsCode`
mirrors the
`plusStep`/`plusIdx` iteration pattern: it walks `k = 0, ..., N-1`, consing `k` onto the
running coded
list (`Nat.pair k acc + 1`, matching `decodeList`'s own `c + 1` |> `c.unpair.1 :: decodeList c
.unpair.2`)
exactly when `n.testBit k`. -/

/-! ## `fun` and `graph` (Exercise 5.14) are computable

The last piece of Exercise 7.23. `PN.Element ? Set Nat` via `elemSet` (established above),
  matching
  Exercise 5.14's classical powerset model `P? = (Set Nat, subseq)`. We reuse Exercise 5.14's
  combinators
  `tag`/`Fun`/`Graph` verbatim, transported to the neighbourhood level by the same "reversal"
  idiom as
  `capMap`/`cupMap`/`plusMap`: a neighbourhood-level combinator tests `Z? subseq h(X?, Y?)`
  for the
  appropriate finite-set operation `h`. For `fun` this `h` is literally `Fun` (Exercise 5.14); `
  funMap`
  is then the `curry` of the resulting two-variable map `gMap : PN x PN -> PN`, so its
  computability is

```

```

*free* from `Theorem75.curry_isComputable` once `gMap` is shown computable. `graph` needs its
own
direct construction (it does not factor through `curry`/`eval`), built from the canonical
witness list
`decodeList (bitsCode j j)` for the excluded set `E?` of a domain neighbourhood `nbhd j`. -/

/-! ### `num`/`tag` are primitive recursive -/

/-! ### `untagList`/`untagVal`: `untagRef`, made primitive recursive

Same "bounded iteration, no-op once done" device as `bitsCode`/`plusIdx`/`tagCode`: pack a
state
` (code, done, revAcc, val)`; each step peels one `unnum` layer of `code` (consing onto `revAcc`
`,
coded via `appendStep`'s convention) until `unnum`'s first component is `0`, at which point `
done`
is set and the state freezes. Since `code` strictly decreases every non-frozen step
(`unnum_snd_lt_of_fst_succ`), `c + 1` iterations always suffice to freeze starting from `code =
c`. -/

/-- The state-transition step: no-op once `done`; otherwise peel one `unnum` layer. -/

/#!/ ### `graph`, dually to `gMap` -/

/-- `GraphIdx W`: the domain-theoretic "positive content" of `graph(W)`, mirroring Exercise
  5.14's
`Graph f = {tag ns m ? m in f (entries ns)}`, but phrased at the level of neighbourhood
  relations and
tested against *every* map `f` in `W` (Scott's "guaranteed regardless of which `f` in `W`"
  idiom, as in
`eval`s `forall f in F, f.rel X Y`). The "argument" is canonically `tagOfBits n m = tag (
  decodeList
  (bitsCode n n)) m` (`decodeList (bitsCode n n)` has entries exactly `E_n`, `mem_bitsCodeList`,
  so it
ranges over the countably many finite sets `(nbhd n)?` rather than over arbitrary lists --
  exactly the
finite-set arguments `Graph` needs, up to the reindexing already used throughout this file.
  Using the
*primitive-recursive* list `bitsCode n n` (rather than the merely well-founded `bitsList n`) is
  what
makes the decode direction (`mem_GraphIdx_iff` below) computable. -/
def GraphIdx (W : Set (ApproximableMap PN PN)) : Set Nat :=

# Exercise 7.24 (Scott 1981, PRG-19, S7) -- the LUCID system `L`

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Lecture VII.

> **Exercise 7.24.** (Suggested by the LUCID language of Ashcroft and Wadge: *SIAM Jour. Comp.*
> vol. 5 (1976).) Define a set `Gamma` by
>
> `Gamma = ?_i ({i} x Gamma) U {*}`.
>
> Define a system `L = {Gamma} U {{i} x X ? i in Nat and X in L}`. Show that `L` is
> effectively given.
> Show that the elements of `|L|` can be identified with the finite and infinite sequences of
> natural numbers. What is the connection between `B` and `L`? Show that the combinators of
> LUCID
> can be construed as computable mappings of type `(L -> T) -> (L -> T)` or of type

```

```
> `(L -> T) x (L -> T) -> (L -> T)`. Conclude that programs in LUCID define computable maps
.
```

```
## What this file proves
```

Scott's ``Gamma`` satisfies a **coinductive** set equation ``Gamma` ~= 1 + (Nat x Gamma)``: an element is either the basepoint ``*`` or a pair ``(i, ?)`` with ``?`` in `Gamma`` again. Taking the *\*\*final\*\** (as opposed to *initial*) solution -- so that the recursion may run forever -- identifies ``Gamma`` with the finite-or-infinite sequences of naturals directly:

```
* **`Gamma` := List Nat ? (Nat -> Nat)`** -- a finite sequence (`inl`, terminating at `*`) or
  an infinite
  one (`inr`, a stream that never reaches `*`). **`star`**/**`cons`** realize `*/`(i, ?)`;
  **`Gamma_cases`** is the defining equation read as a theorem (every `?` is `star` or a unique
  `cons i ?`), and **`cons_injective`** is the "unique" half.
* **`consSet i X = {i} x X`** and **`nbhd l`** (`nbhd [] = Gamma`, `nbhd (i :: l) = {i} x
  nbhd l`) --
  exactly Scott's neighbourhoods, indexed by the finite list of naturals `l` that names them
  (mirroring `ExampleB.cone`/`Example62.embBit`, generalized from `Bool` to `Nat`-ary branching
  ).
  **`nbhd_subset_iff`** (`nbhd l subseq nbhd l' <=> l' <+: l`) is the master reduction,
  giving
  **`Lmem`**'s nested-or-disjointness (`L_nestedOrDisjoint`) and hence the system **`L`**.

theorem L_isEffectivelyGiven : L.IsEffectivelyGiven := <Lpres>

/! ## Exercise 7.24, second claim -- `|L|` is the finite-or-infinite sequences

`toElement : Gamma -> L.Element` sends a finite list `l` to the *principal* filter `(nbhd l)`
(Scott's finite elements), and an infinite stream `f` to the *limit* filter of its finite
prefixes (`streamElement`, an instance of Scott's `limitFamily`, Definition 1.6's prose).
`toElement_bijective` shows this identification is exact: injectivity is choice-free (finite vs
finite is `nbhd_injective`; finite vs. infinite is separated by `HasMin`, "having a smallest
neighbourhood", which the finite elements have and the infinite ones provably don't;
infinite vs. infinite recovers `f` pointwise from its prefixes). Surjectivity genuinely needs
choice (build the infinite witness sequence one coordinate at a time; flagged below), matching
Scott's "***can be identified with**" (an existence claim, not a computable retraction). -/

/-- The length-`n` prefix of an infinite stream `f`: `finPrefix f n = [f 0, ..., f (n - 1)]`.

/-! ## Exercise 7.24, third claim -- the connection between `B` and `L`

Scott's binary system `B` (`ExampleB.lean`) branches over `Bool = {0,1}` at each node
(`Sigma* = ?_b {b} x Sigma* U {?}`); `L` branches over all of `Nat` (`Gamma = ?_i {i} x
Gamma U {*}`). **`L` is `B`

```

```

generalized from  $2$ -ary to  $\text{Nat}$ -ary branching** -- concretely, digit-wise embedding the bits
`0, 1`
as the naturals  $0, 1$  identifies  $B$  with the sub-system of  $L$  consisting of addresses built
from
only the two digits  $\{0, 1\}$ . `embStr_prefix_iff`/`cone_subset_cone_iff_nbhd_embStr` make this
precise: the embedding `embStr : Sigma* -> List Nat` is an order-embedding of the prefix
posets, hence
(via `nbhd_subset_iff`/`cone_subset_cone`) of the neighbourhood-inclusion posets, hence (via
`principal_le_iff`) of  $|B|$ 's finite elements into  $|L|$ 's (`
sigmaBot_le_iff_toElement_inl_embStr`).
The same digit-wise embedding on infinite streams (`Nat -> Bool ? Nat -> Nat`) identifies
Scott's *infinite*
binary sequences with the `Nat -> Nat`-branch of  $\Gamma$  whose values happen to lie in  $\{0, 1\}$ ,
by the same
argument as `toElement`'s `Sum.inr` case --  $B$ 's domain  $|B|$  sits inside  $|L|$  as the sub-
domain of
"binary-valued" LUCID sequences. -/

/-! ## Exercise 7.24, fourth claim -- LUCID combinators as computable maps

> Show that the combinators of LUCID can be construed as computable mappings of type
> `(L -> T) -> (L -> T)` or of type `(L -> T) x (L -> T) -> (L -> T)`. Conclude that
    programs in LUCID define
> computable maps.

`T` is Example 1.2's three-point truth-value domain (`Example23.T`). We give it a computable
presentation `Tpres` (three neighbourhoods, enumerated by hand -- the tiniest instance of
    Definition
7.1), then show two representative LUCID-style combinators are computable: pointwise **negation
**
`notT : T -> T` and pointwise **conjunction** `andT : T x T -> T`. The general engine is
    the pair of
*lifting* theorems `postcompose`/`pointwiseBin`: any computable `h : V_1 -> V_2` lifts to a
    computable
map `(L -> V_1) -> (L -> V_2)` via `curry (h comp eval)` (Scott's `postcompose`), and any
    computable
`h : V_0 x V_1 -> V_2` lifts to a computable `(L -> V_0) x (L -> V_1) -> (L -> V_2)` by
    evaluating both factors at
the same argument and applying `h`. Since `comp_isComputable`/`paired_isComputable` close
    computability under composition and pairing (Proposition 7.3, Theorem 7.4), **every** LUCID
    program
built from such combinators -- however deeply composed -- again defines a computable map. This
    is the
choice-free core of the claim; assembling one concrete presentation of `(L -> T)` to state it
    against
uses `Classical.choice` exactly once (to extract concrete characteristic functions from the
    existential
deciders of `Lpres`/`Tpres`), matching the classical bridge already used for `
    toElement_surjective`.

/#!/ ### The general lifting engine: `postcompose` and `pointwiseBin`

Any computable `h : V_1 -> V_2` lifts to a computable `(L -> V_1) -> (L -> V_2)` (Scott
's `postcompose`,
`curry (h comp eval)`), and any computable `h : V_0 x V_1 -> V_2` lifts to a computable
`(L -> V_0) x (L -> V_1) -> (L -> V_2)` (`pointwiseBin`, evaluating both factors at
the same argument and
applying `h`). Stating either against a *concrete* presentation of the relevant function space(s)
needs a bundle of characteristic functions for `funPresentation Lpres P`; `LFunData` packages
exactly that bundle, and `LFunData.ofPresentation` extracts one from an arbitrary
`P : ComputablePresentation V`, using `Classical.choice` exactly once per component
presentation (to
pull concrete deciders out of `P.incl_computable`/`P.cons_computable`/`P.eq_computable`'s
existentials
-- the same classical bridge already used for `funSpace_isEffectivelyGiven`, just packaged so
it can be
*named* and reused as data rather than immediately discharged into a `Prop` goal). -/

/-! ### Conclusion: the LUCID combinators `notT`/`andT` lift to computable `(L -> T)` maps

One concrete choice of `LFunData Tpres` (`LTdata`, via `Classical.choice`) presents `(L -> T)`
(`LTpres`); `notT`/`andT`'s computability (already established, choice-free) transports through
`postcompose`/`pointwiseBin` to give computable maps of exactly Scott's two stated types,
`(L -> T) -> (L -> T)` and `(L -> T) x (L -> T) -> (L -> T)`. Since `comp_isComputable`/`
paired_isComputable` close
computability under composition and pairing, any LUCID program built from these (and their
kin,
built the same way from any other computable `T`-combinator) -- however deeply composed --
again
defines a computable map on `(L -> T)`; `deMorganT_isComputable` below composes both lifted
combinators
together `(not (not f /\ not g))`, De Morgan's law for the sequential `and`) as a concrete
witness of this
closure. -/

/-- The one concrete presentation of `(L -> T)` used to state the LUCID combinators'
computability. -/
noncomputable def LTdata : LFunData Tpres := LFunData.ofPresentation Tpres

/-- The computable presentation of `(L -> T)`. -/
noncomputable def LTpres : ComputablePresentation (funSpace L Example23.T) := LTdata.pres

/-- Exercise 7.24, fourth claim, `notT` case. LUCID's pointwise negation lifts to a
computable
map of type `(L -> T) -> (L -> T)`. -/
theorem notT_lifted_isComputable : IsComputableMap LTpres LTpres (postcompose notT) :=
  postcompose_isComputable LTdata LTdata notT_isComputable

/-- Exercise 7.24, fourth claim, `andT` case. LUCID's pointwise (sequential) conjunction
lifts to
a computable map of type `(L -> T) x (L -> T) -> (L -> T)`. -/
theorem andT_lifted_isComputable :
  IsComputableMap (prodPresentation LTpres LTpres) LTpres (pointwiseBin andT) :=
  pointwiseBin_isComputable LTdata LTdata LTdata andT_isComputable

/-- A deeper LUCID program is still computable. `deMorganT f g := not (not f /\ not g)`
on `(L -> T)`,
built by composing/pairing the two lifted combinators above (De Morgan's law for the sequential
`and`); it is computable purely by the closure lemmas `comp_isComputable`/`paired_isComputable`
,
with no fresh recursion-theoretic argument needed -- exactly Scott's "conclude that
programs in
LUCID define computable maps." -/

# Lecture VIII -- Definition 8.1 (Scott 1981, PRG-19): retractions

Lecture VIII embeds every domain of interest into one "largest" domain, the universal domain
`?`
of Definition 8.7. Before constructing `?` itself, Scott studies how a subdomain `D ? E`
corresponds to a self-map of `E` -- a retraction. As Scott remarks, this analysis lets every
domain-theoretic construction be re-expressed as a fun -calculus combinator (culminating in
the
`sub` combinator of Theorem 8.6).

**Definition 8.1.** A retraction of a domain `E` is an approximable mapping `a : E -> E`
such that
`a comp a = a`.

This module states the definition and the handful of elementary closure facts (`idMap` is
always a
retraction; retractions are closed under nothing further at this level of generality -- the
interesting closure facts come from Proposition 8.2 onward).

Everything here is choice-free (`#print axioms subseteq {propeq, Quot.sound} `).

Lecture VIII -- Proposition 8.2 (Scott 1981, PRG-19): $D \rightarrow E$ induces a retraction

Proposition 8.2. If $D \rightarrow E$ and $a : E \rightarrow E$ is defined by

$X \ a \ Z$ iff $\exists Y \text{ in } D. X \subseteq Y \subseteq Z$

for all $X, Z \text{ in } E$, then a is a retraction and $|D|$ is isomorphic to the fixed-point set of a ,

$\{y \text{ in } |E| \mid a(y) = y\}$, under inclusion.

The construction

Scott's own proof observes that the relation above is exactly $a = i \circ j$, where $i : D \rightarrow E$,

$j : E \rightarrow D$ are the injection/projection of Proposition 6.12 (`Subsystem.inj`/`Subsystem.proj`).

We take this as the *definition* (`retractionOfSubsystem`), which makes both halves of the theorem

short calculations with the category laws of Theorem 2.5:

a is a retraction. $a \circ a = i \circ j \circ i \circ j = i \circ (j \circ i) \circ j = i \circ \text{id} \circ j = i \circ j = a$, using

`Subsystem.proj_comp_inj : j \circ i = I_D` (`isRetraction_retractionOfSubsystem`).

$|D| \cong \text{Fix}(a)$. The forward map $x \mapsto i(x)$ lands in $\text{Fix}(a)$ because $a(i(x)) = i(j(i(x))) = i((j \circ i)(x)) = i(x)$; the inverse is $y \mapsto j(y)$, using `Subsystem.proj_comp_inj` again for the round trip $j(i(x)) = x$, and the fixed-point equation

$a(y) = y$ itself (unfolded to $i(j(y)) = y$) for the other round trip. Both i and j are monotone, and applying j to $i(x) \sqsubseteq i(x')$ recovers $x \sqsubseteq x'$ (again via $j \circ i = I_D$), so the

correspondence is an order-isomorphism, not just a bijection (`elementIso`).

Everything here is **choice-free** (`#print axioms subseteq {propx, Quot.sound}`), since Proposition 6.12

and Theorem 2.5 are.

# Lecture VIII -- Definition 8.3 (Scott 1981, PRG-19): projections and finitary retractions

**Definition 8.3.** A retraction `a : E → E` is called a projection provided `a` sqsub 1
  `E`; it is
finitary iff its fixed-point set is isomorphic to a domain.

Scott's remark right before the definition already shows every retraction of Proposition 8.2's
form is a projection: unwinding `X a Z <=> exists Y in D, X subseq Y subseq Z`
  gives `X subseq Z` immediately, i.e.
`a` sqsub 1_E. And Proposition 8.2's other half -- `|D| == Fix(a)` -- says exactly that
  these retractions
are finitary, with `D` itself as the witnessing domain. So every `retractionOfSubsystem h` is
  a
finitary projection (`isProjection_retractionOfSubsystem`, `isFinitary_retractionOfSubsystem`).
Scott's remark that the converse fails ("not every retraction... even this condition is not
sufficient") is the content of Theorem 8.5, formalized separately.

Everything here is choice-free (`#print axioms subseq {propx, Quot.sound}`).

# Lecture VIII -- Theorem 8.5 (Scott 1981, PRG-19): finitary projections via a step-closure
  formula

**Theorem 8.5.** For an approximable mapping `a : E -> E` the following are equivalent:

(i) `a` is a finitary projection;

(ii) `a(x) = {Y in E ? exists X in x, X subseq Y /\ X a X}`, for all `x in |E|`.

## What is formalized here

The *(ii) ? (i)* direction (isFinitaryProjection_of_formula`) is proved in full, and is
  what
Theorem 8.6 actually needs: sub`'s fixed points are by definition exactly the maps a`
  satisfying formula (ii), so characterising the range of sub` only ever needs this direction.

The construction: from a`, build D := {X in E ? X a X}` directly (fixedNbhd`) -- this is a
  genuine
  subsystem D ? E` for any approximable map a` (fixedNbhd_subsystem`), no hypothesis on a`
  needed for the neighbourhood-system axioms themselves. Formula (ii), unwound at principal
  elements
  via rel_iff_mem_principal`, says exactly that a`'s relation matches Proposition 8.2's formula
  for
  D`: a = retractionOfSubsystem (fixedNbhd_subsystem a)`. Proposition 8.2 (via Definition 8.3's
  corollaries) then hands us IsFinitaryProjection a` for free.

The (i) ? (ii)` direction is not formalized in this file. Scott's own proof needs a fact
  not
  yet in the codebase: a section/retraction pair i dashv j` (j comp i = I_D`) built from the
  abstract
  "isomorphic to a domain" witness of IsFinitary` reflects compactness -- if i(w)` is a
  principal
  (finite) element of E` then w` is already principal in D`. (Scott's own remark: "i(j(X)) =
  X`
  means j(X)` is a finite element of D`".) This is provable from existing machinery (
  iSupDirected`/
  toElementMap_iSupDirected` give continuity of i`, and D`'s general algebraicity gives that
  every
  element is a directed union of its principal approximants -- a compact element equalling a
  directed
  sup must already equal one of the sup's members), but assembling it is a standalone, comparably
  sized effort to the rest of this file and is left as a documented follow-up; see HANDOFF.md`.

Everything proved here is choice-free (#print axioms subseq {propxt, Quot.sound}`).

# Lecture VIII -- Theorem 8.6 (Scott 1981, PRG-19): the `sub` combinator

**Theorem 8.6.** For any domain `E` define `sub : (E -> E) -> (E -> E)` by the formula

`X sub(f) Z` iff `exists Y in E. X subseq Y, f Y subseq Z`,

for all `X, Z in E` and all `f : E -> E`. Then the range of `sub` consists exactly of the
finitary
projections on `E`, and moreover `sub` itself is a finitary projection on `(E -> E)`. If `E`
is
effectively given, then `sub` is computable.

## What is formalized here

Scott's formula for `sub(f)` is literally Proposition 8.2's `retractionOfSubsystem`, applied
to
Theorem 8.5's subdomain `D = fixedNbhd f = {Y in E ? Y f Y}` (which, recall, is a genuine
subsystem
`D ? E` for any `f`, no hypotheses needed). This module formalizes the per-token map
`sub : ApproximableMap E E -> ApproximableMap E E` and its order-theoretic content at that
level,
**Theorem 8.6's clause 1 in full**:

* **`sub f <= f`** (`sub_le`) -- Scott's "`X subseq Y, f Y subseq Z` always implies `
X f Z`", a bare
monotonicity calculation, valid for any `f`.
* **`sub` is idempotent, exactly: `sub (sub f) = sub f`** (`sub_sub`) -- sharper than Scott's
stated
inclusion `sub(f) subseq sub(sub(f))`: unwinding `fixedNbhd (sub f)` shows it has the
same
neighbourhoods as `fixedNbhd f` (`Y subseq Y' subseq Y` forces `Y = Y'`), so `sub (
sub f)` and `sub f` are
built from literally the same subsystem and hence are equal, not just related by `<=`.
* **`sub` is monotone** (`sub_mono`) -- immediate from `fixedNbhd`'s definition.
* **`range(sub) = finitary projections`, both directions** (`
sub_eq_self_iff_isFinitaryProjection`):
the easy half `sub f = f -> IsFinitaryProjection f` (`isFinitaryProjection_of_sub_eq_self`)
is
immediate substitution into `Subsystem.isFinitaryProjection_retractionOfSubsystem`; the
converse
`IsFinitaryProjection f -> sub f = f` (`sub_eq_self_of_isFinitaryProjection`) is now
unblocked by
Theorem 8.5's hard direction (`formula_of_isFinitaryProjection`): `sub_le` gives `subseq`
for free, and
`subseq` unwinds `X f Z` via `rel_iff_mem_principal` into `Z in f(X)`, then rewrites
via Theorem 8.5's
formula into exactly `sub_rel`'s defining shape.
* **`sub f` is always a finitary projection**, for any `f` (`isFinitaryProjection_sub`) --
`sub (sub f) = sub f` plus the above.

**Theorem 8.6's clause 2, in full (in `namespace Sub8_6`):** `sub` packaged as a genuine
`ApproximableMap (funSpace E E) (funSpace E E)` (`subApprox`), realizing Scott's remark that
"the correspondence `f |> sub(f)` preserves directed unions of `f`'s, thus `sub` is itself
approximable", and shown to be a finitary projection on `(E -> E)`
(`isFinitaryProjection_subApprox`):

```

```

`subApprox` is built via Exercise 2.13's `ofContinuous`, using a new general domain-theory
  bridge
`continuous_of_monotone_iSupDirected` (`Exercise213.lean`: monotone + directed-sup-preserving ?
topologically continuous, proved directly from algebraicity) applied to `subFilter`, `sub`
transported along `funSpaceEquiv`. `subFilter`'s directed-sup-preservation
(`subFilter_iSupDirected`) needs no consistency argument at all: directed unions of *filters*
correspond, under `toApproxMap`, to the raw union of the underlying maps' *relations*
(`toApproxMap_rel_iSupDirected`, immediate from `mem_iSupDirected`), and `sub`'s formula is a
*positive* existential in `f`'s relation, hence commutes with such unions by pure logic
(`sub_toApproxMap_iSupDirected`). `IsRetraction subApprox`/`subApprox` <= `idMap` then drop out
  of
`sub_sub`/`sub_le` respectively (`isProjection_subApprox`).

**`IsFinitary subApprox`** (`isFinitary_subApprox`) turned out *not* to need the universal-
  domain
machinery after all: `finitaryProjectionSubsystemEquiv` upgrades Theorem 8.6(a)'s bijection
`f |-> fixedNbhd f` / `D |-> retractionOfSubsystem D` between `{f ? sub f = f}` and the
  subsystems
`{D ? D ? E}` into a genuine **order-isomorphism** (round trips `
  fixedNbhd_retractionOfSubsystem`
and `sub`'s own defining equation; order via `retractionOfSubsystem_rel`'s witness clause plus
`Subsystem.subsystem_iff_subset_of_common`). Composed with `Fix(subApprox)` ?o `{f ? sub f = f}`
(`subApproxFixIso`, via `toApproxMap`/`toFilter`) and **Lecture VI's Proposition 6.11**
(`subsystemReprIso`: the subsystems of `E` already form a genuine domain), this gives the
  witness
for `IsFinitary subApprox` directly, with no new "domain of subsystems" construction needed.

**Not formalized (deferred):**

* **Clause 3 (computability)** -- needs `E` effectively given (Def 7.1 machinery); a separate,
  not-yet-formalized prerequisite.

Everything proved here is **choice-free** (`#print axioms subseq {propext, Quot.sound}`), *
  except*
`isFinitary_subApprox`/`isFinitaryProjection_subApprox`, which pick up `Classical.choice`
  solely
through Proposition 6.11's `subsystemReprIso` (itself inheriting it from Exercise 2.22's `
  reprIso`,
the documented "for set theorists" exercise) -- the same, already-accepted, provenance as every
other domain-representation result in this project (Ex 3.25/3.27, Prop 6.11 itself).

  isFinitaryProjection_of_sub_eq_self (sub_sub f)

/-! ## The finitary-projections-on-`E` <-> subsystems-of-`E` order-isomorphism

Needed below for `Sub8_6.isFinitary_subApprox` (Theorem 8.6(b)(ii)): the bijection `f |->
fixedNbhd f`
/ `D` |-> retractionOfSubsystem `D` between `{f ? sub f = f}` (the finitary projections) and
`{D ? D ? E}` (the subsystems) that already underlies `sub`'s definition is in fact an
order-isomorphism. Composed with Proposition 6.11's `subsystemReprIso` (the subsystems of `E`
already form a genuine domain, from Lecture VI), this gives Theorem 8.6(b)(ii)'s witness
directly --
no new "domain of subsystems" construction is needed here. -/

/-- `fixedNbhd (retractionOfSubsystem h) = D` : the round trip recovering a subsystem `D` from
the
retraction it induces. `Y (retractionOfSubsystem h) Y <-> exists W in D, Y subseq W
subseq Y`, and `Y subseq W subseq Y` forces `W=Y`, so
this says exactly `D.mem Y` (using `E.mem Y` for free from `D subseq E`). -/
theorem fixedNbhd_retractionOfSubsystem {D : NeighborhoodSystem a} (h : D ? E) :
  fixedNbhd (Subsystem.retractionOfSubsystem h) = D := by

/-! ## Theorem 8.6, clause 2 (partial): `sub` is itself approximable, and a projection, on
`(E → E)`

Scott's remark: "the correspondence `f` |-> sub(f)` preserves directed unions of `f`'s, thus `
sub`
is itself approximable". We realize this via Exercise 2.13 (`ofContinuous`): transported along
`funSpaceEquiv` to `subFilter : (funSpace E E).Element → (funSpace E E).Element`, `sub` is
monotone
(`subFilter_mono`, from `sub_mono`) and preserves directed unions (`subFilter_iSupDirected`) --
the
latter because `sub`'s defining formula (`sub_rel`) is a *positive* existential in `f`'s
relation,
so it commutes with the raw union of relations that `toApproxMap` assigns to a directed union
of
filters (`toApproxMap_rel_iSupDirected`, immediate from `mem_iSupDirected`), with no extra
consistency argument needed. `continuous_of_monotone_iSupDirected` then upgrades this to
genuine
topological continuity, giving `subApprox := ofContinuous subFilter hc`.

```

`IsFinitary subApprox` (further below) needs no new "domain of subsystems" construction: it composes `Fix(subApprox) ?o {f ? sub f = f}` (`subApproxFixIso`) with the `finitaryProjectionSubsystemEquiv`/`subsystemReprIso` route already available from Theorem 8.6(a)

and Lecture VI's Proposition 6.11.

****Not yet formalized:**** the computability clause (Theorem 8.6's clause 3), which needs `E` effectively given (Def 7.1 machinery), a separate prerequisite. -/

# Theorem 8.6(c) (Scott 1981, PRG-19, Lecture VIII) -- `sub` is computable

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Theorem 8.6's
third clause: *"If `E` is effectively given, then `sub` is computable."* Here "`sub`" means the
combinator packaged as an approximable map on the function space (`Sub8_6.subApprox` :
  ApproximableMap
  (funSpace E E) (funSpace E E)`, Theorem 8.6(b)(i)), and "computable" is relative to the
function-space presentation that Theorem 7.5 builds out of any presentation of `E`.

## Strategy (choice-free), mirroring Theorem 7.6's `fixMap_isComputable`

`subApprox` was built via Exercise 2.13's `ofContinuous`, so its neighbourhood relation unfolds
(via `ofMono`) to: `subApprox.rel F G <=> exists hF : (funSpace E E).mem F, sub (toApproxMap
  (F)).mem
  G`-ish, i.e. (using `toFilter`'s definition) `F subApprox G` holds iff `sub` of `F`'s least map
  lies
  in* `G` as a literal set of approximable maps (`subApprox_rel_iff`). Specializing `F = Xenum n
  `,
  `G = Xenum m` (Theorem 7.5's enumeration) and unfolding membership via `mem_Xenum_iff_map`:

  `(Xenum n) subApprox (Xenum m)` iff, for every coded step `
```

```

Lecture VIII -- Examples 8.4 (Scott 1981, PRG-19): ``check``/``fade`` and the two-point retraction

Scott's **EXAMPLES 8.4** is really three worked examples built from the *same* pair of combinators ``check``/``fade``. This file formalizes the first, headline example, labelled **Example 8.4(a)** in ``arxiv.md``; the other two (``strict``/``smash`` as projections, Example 8.4(b))

are a separate, larger effort building on the same ``check``/``fade`` machinery -- see the strategy note on the 8.4(b) row of ``arxiv.md``.

Example 8.4(a). If a system ``D`` is not trivial (there is some ``u`` in `|D|`` with ``u``  $\neq$  `False``), then the two-element system ``O`` = $\{\{0\}, \{0,1\}\}$ arises from a retraction on ``D``. Scott's construction:

* ``check`` : `D` $\rightarrow$ `O`` by ``X`` check `Y`` $\leftrightarrow$ `Y`` =  $\{0,1\}$   $\vee$  `X`` $\neq$ `Delta``. So ``check(x)`` = `False_0`` iff ``x`` = `False_D``.

* ``fade`` : `O``  $\times$  `D`` $\rightarrow$ `D`` (left to the reader) by ``fade(t, x)`` = `False_D`` if ``t`` = `False_0``, else ``x``.

* Fix any ``u`` $\neq$ `False_D`` and set ``a(x)`` = `fade(check(x), u)``. Then ``a`` is a retraction (not generally a projection) and the range of ``a`` is isomorphic to ``O``.

Formalization strategy

* ``O`` is built directly as a ``NeighborhoodSystem`` (Fin 2) with ``mem`` = $\{\{0\}, \{0,1\}\}$.

* ``check`` is built as a literal ``ApproximableMap`` `D O`` from Scott's formula (a ``Prop``-valued relation, no case-splitting/decidability needed for the *definition* itself).

* ``fade`` is built via the two-variable bridge ``ApproximableMap_2``/``ofMap_2`` (Theorem 3.5): the two-variable relation ``fade_2`` : `ApproximableMap_2 O D D`` is ``Z`` = `Delta_D`` $\vee$ (`X`` =  $\{0\}$   $\wedge$  `Y`` $\subseteq$ `Z``) -- the

disjunct ``Z`` = `Delta_D`` is always a safe ("least informative") output regardless of the `O``-input,

and ``X`` = $\{0\}$ $\wedge$ `Y``  $\subseteq$  `Z`` is the "pass ``x`` through" branch.

* ``a`` := `fade.comp`` (paired `check`` (`constMap`` `D u``)) is Scott's literal composite. Unfolding it via ``toElementMap_comp``/``toElementMap_paired``/``toElementMap_constMap``/the ``ApproximableMap_2`` bridge

gives the clean closed form ``mem_toElementMap_a``: ``a(x)`` ? `Z``  $\leftrightarrow$  `Z`` = `Delta_D``  $\vee$  (`x`` $\neq$ `False_D``  $\wedge$  `u`` ? `Z``) -- i.e.

literally "``a(x)`` = `False_D`` if ``x`` = `False_D``, else ``u``" (``a_bot``, ``a_of_ne_bot``).

* From the closed form, ``IsRetraction a`` is immediate case analysis (``x`` = `False`` is fixed at `False``;

``x`` $\neq$ `False`` lands on ``u``  $\neq$  `False``, itself fixed).

* The fixed-point set is exactly $\{\text{False}_D, u\}$. Rather than characterizing it abstractly, the isomorphism to ``O`` is built *directly* and choice-freely from the same closed-form data:

``fixOf0 t`` (for ``t`` : `O.Element``) is the filter ``Z``  $\mapsto$  `Z`` = `Delta_D``  $\vee$  (`t`` ? $\{0\}$ $\wedge$ `u`` ? `Z``)

(the "plug ``t``'s informativeness into ``a``'s formula" filter -- a genuine ``Element``, no ``if``/``Classical.choice`` in

the *data*), and ``invOfFix y`` := `check.toElementMap y``. The round-trip/order-preservation facts

needed for the ``OrderIso`` are proved from the closed forms; a few individual ``Prop``-level steps

use classical case splits (``by_contra``/``push_neg``), consistent with the project's choice discipline (data stays choice-free; supporting propositions may use ``Classical.choice``,

```

    flagged
    in the axiom audit recorded in `HANDOFF.md`).

Lecture VIII -- Example 8.4(b) (Scott 1981, PRG-19): `smash` and `strict` as projections

The remainder of Scott's **EXAMPLES 8.4**, building on Example 8.4(a)'s `check`/`fade` combinators
(`Scott1980/Neighborhood/Example84.lean`):

```

**`smash : D x E -> D x E`, `smash(x, y) = fade(check(x), fade(check(y), <x, y>))`,
is a
*projection* on `D x E` whose range is isomorphic to the smash product `D ? E` (Exercise
5.10).
**`strict : (D -> E) -> (D -> E)`, `strict(f) = fun x. fade(check(x), f(x))`, is a *
projection* on
the function space `(D -> E)` whose range is isomorphic to the strict function space `D ->
False E`
(Exercise 5.10).

```

Formalization strategy

Both combinators reuse `check`/`fade` **verbatim** (they are already generic over the ambient codomain of `fade` and the ambient domain of `check`), reinstantiated at a second neighbourhood system: `fade (D := prod D E)`/`fade (D := E)` and `check (D := D)`/`check (D := E)`. No new `ApproximableMap`-level combinator is built from scratch; the whole file is `comp`/`paired`/`proj` bookkeeping plus the accompanying closed-form calculations, exactly as in 8.4(a).

`smash`. The key move is *reduction to Proposition 8.2*: `Exercise510.smash D E` (the smash-product neighbourhood system) is a genuine *subsystem* of `prod D E` (`smash\_subsystem\_prod`) -- every smash neighbourhood is a product neighbourhood, and a proper smash neighbourhood stays proper (hence still a smash neighbourhood) after any intersection that lands back inside `prod D E` (`Exercise510.inter\_ne\_master\_left/right` do the heavy lifting, exactly as in `Exercise510.smash`'s own closure proof). Scott's literal combinator is built first and its closed form derived directly (`smashRetraction\_mem\_iff` -- literally "leave `z` alone if neither coordinate is `False`, else collapse to `False`"); it is then identified with `Subsystem.retractionOfSubsystem smash\_subsystem\_prod` (`smashRetraction\_eq\_retractionOfSubsystem`, the one genuinely new argument -- a "compactness" calculation packing a witness neighbourhood of the smash out of any pair of non-`False` witnesses via `z.fst`/`z.snd` filter algebra), after which `IsProjection`/`IsFinitary`/the isomorphism to `Exercise510.smash D E` are *all* inherited for free from Definition 8.3's `Subsystem` corollaries.

`strict`. Built directly as `curry (fade.comp (paired (check.comp proj\_1) evalMap))` using Theorem 3.12's `curry`/`evalMap` (no new function-space machinery needed -- `curry` already exists). Its closed form (`toApproxMap\_strictRetraction\_apply`) says exactly "`strict(f)(y) = False\_E` if `y = False\_D`, else `f(y)`", from which: (a) `f` is a fixed point of `strict` iff `f(False) = False`, i.e. iff `IsStrict f` (`strictRetraction\_fixed\_iff`); (b) restricting `funSpaceEquiv` along this correspondence gives `Fix(strict) ?o {f ? IsStrict f} = StrictMap D E` (`strictRetractionFixIso`), which composed with `Exercise510.strictFunEquiv.symm` gives the isomorphism to `Exercise510.strictFun D E` announced by Scott.

Everything is **choice-free** in the *data* (`smashRetraction`, `strictRetraction`); the packaged `OrderIso`s and the `IsRetraction`/`IsProjection` *proofs* pick up `Classical.choice` only through `by\_contra`/`by\_cases` case splits, exactly mirroring 8.4(a)'s discipline.

# Definition 8.7 (Scott 1981, PRG-19, Lecture VIII) -- the universal domain `?` over `?`

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Definition
8.7:

> Let `?` be the set of rational numbers, and let  $[0,1) = \{q \text{ in } ? \mid 0 \leq q < 1\}$ , and
  similarly for
>  $[r,s)$  for any  $r < s$  in `?`. The neighbourhood system `?` over  $[0,1)$  is the set of all
> non-empty finite unions of rational intervals  $[r,s)$  with  $0 \leq r < s \leq 1$ .

## Encoding

A finite union of intervals is coded by a `List (α × α)` of endpoint pairs
(`presentedIntervals L := { p in L, Set.Ico p.1 p.2 }`). Rather than build the endpoint bounds
 $0 \leq r < s \leq 1$  into the *list* (which would force bookkeeping through every list
operation), we
build  $?.\text{mem } X$  from the *unconstrained* presentability of  $X$  plus the two set-level
conditions
Scott's family actually cares about:  $X$  is non-empty and  $X \subseteq [0,1)$ . mem_iff_scott
below shows
this is no relaxation at all: it is *equivalent* to Scott's literal per-pair-bounded
description,
since clipping any presenting list to  $[0,1)$  and discarding degenerate (empty) pairs changes
neither the represented set nor its non-emptiness/inclusion in  $[0,1)$ .

The point of this encoding is that closure under intersection becomes endpoint-bookkeeping-free
:
`Set.Ico_inter_Ico` says  $\text{Ico } a_1 \ b_1 \ \cap \ \text{Ico } a_2 \ b_2 = \text{Ico } (a_1 \sqcup a_2) \ (b_1 \sqcap b_2)$ 
`*unconditionally*` (the
result is simply empty when the sup/inf bounds cross), so pairwise-combining two presenting
lists
(`combineIntervals`) always presents the intersection, with no case split on validity.

## Axiom footprint

Every proof here is elementary finite-list recursion plus the linear order on `?` -- no genuine
appeal to choice is made. However, #print axioms reports [propext, Classical.choice,
Quot.sound] throughout, because the *pinned Mathlib's* bundled order instance for `?`
(Rat.instLinearOrder in Mathlib.Algebra.Order.Ring.Unbundled.Rat) is itself
Classical.choice-tainted at the axiom level -- even Rat.le_refl reports this footprint in
this
Mathlib snapshot (confirmed directly, and also for the pre-existing Exercise117.lean, whose
ratIntervalMem_nonempty is likewise Classical.choice-tainted despite that file's now-stale
"choice-free" docstring claim). This is an upstream artifact of `?'s order hierarchy, not a
```

```

choice made in this file; nothing here uses `Classical.choice`, `Classical.dec`, or any
non-constructive existence principle directly.

# A choice-free Gödel numbering of  $\mathbb{Q}$ , with primitive-recursive comparison/max/min

Theorem 8.8(b) (Scott 1981, PRG-19) needs  $\mathbb{Q}$  (Definition 8.7) to have a genuine
`ComputablePresentation` (Definition 7.1).  $\mathbb{Q}$ 's neighbourhoods are finite unions of rational
intervals `presentedIntervals L` for  $L : \text{List } (\mathbb{Q} \times \mathbb{Q})$ , so we first need  $\mathbb{Q}$  itself -- and
hence
`List (\mathbb{Q} \times \mathbb{Q})` -- coded by naturals, with the arithmetic operations `combineIntervals`
actually
performs ( $\text{sqsup}$ ,  $\text{sqcap}$ ,  $\leq$ ,  $=$ ) realized as genuinely  $\text{Nat.Primrec}$  functions on
the codes.

## The encoding

An integer  $z : \mathbb{Z}$  is coded as an (unnormalized) difference pair  $\text{Nat.pair } z.\text{toNat } (-z).\text{toNat}$ 
-- deliberately not a zig-zag bijection, since a difference pair turns every integer
comparison
into a cross-addition of naturals ( $a_1 - b_1 \leq a_2 - b_2 \iff a_1 + b_2 \leq a_2 + b_1$ )
, avoiding truncated
subtraction (and its case splits) entirely in the downstream  $\text{Nat.Primrec}$  proofs. A rational
 $q : \mathbb{Q}$  is coded as  $\text{Nat.pair } (\text{encodeInt } q.\text{num}) (q.\text{den} - 1)$  (the  $-1/+1$  shift keeps the
denominator positive without a separate side condition). Both round-trip exactly on every
input
( $\text{decodeInt\_encodeInt}$ ,  $\text{decodeRat\_encodeRat}$ ), not just on some "canonical" sub-class of codes
--
mirroring  $\text{Recursive.lean}$ 's  $\text{decodeList\_encodeList}/\text{encodeList\_decodeList}$  exact round trips,
and
for the same reason: it lets downstream code freely compose  $\text{encode} \circ \text{comp} \circ \text{decode}$  without
tracking a
canonicity invariant.

 $\text{decodeRat}$ 's surjectivity ( $\text{decodeRat\_surjective}$ ) is what lets  $\mathbb{Q}$ 's presentation enumerate every
rational, and  $\text{mkRat\_self}$  (core Lean, choice-free) is the only fact about  $\text{Rat}$ 's internal
normalization we need.

## Primitive-recursive comparison arithmetic

 $\text{ratLeCode}/\text{ratLtCode}/\text{ratEqCode}$  decide  $\leq /< / =$  between two rational codes by cross-
clearing
denominators (again via addition, not subtraction, exactly as for  $\mathbb{Z}$ );  $\text{ratMaxCode}/\text{ratMinCode}$ 
select one of the two input codes via  $\text{Domain.Recursive.selectFn}$ , mirroring
 $\text{Domain.Recursive.primrec\_max}$ 's pattern exactly.  $\text{zeroCode}/\text{oneCode}$  are fixed codes for the
constants  $0, 1 : \mathbb{Q}$  used by  $\text{Definition87.lean}$ 's  $\text{clip}$ .

Everything here is  $\text{subseq} \{ \text{propext}, \text{Quot.sound} \}$  -- no  $\text{Classical.choice}$  -- since it is
all direct
```

```

`Nat.Primrec` construction and finite case-splitting on ` $\leq$ ` (decidable, not classical,
  for `Int`
and `?`).

`ratMidCode (pair c_1 c_2)` codes `(decodeRat c_1 + decodeRat c_2) / 2` **without performing
any
division**: cross-clearing denominators as in `ratLeCode` turns the sum into a single fraction
over
`d_1*d_2`, and halving a fraction is simply *doubling its denominator* (`n/d / 2 = n/(2d)`), so
no
`gcd`/reduction step is ever needed -- `decodeRat`'s own `mkRat` call normalizes the result. -/

/-- The midpoint code `(c_1+c_2)/2` of two rational codes, via denominator cross-clearing (as

  encodeList`

```

```

convention) and a primitive-recursive binary operation `bop`, produce the code of the list of
  all
`bop x y` for `x` ranging over `c1`'s list and `y` over `c2`'s list.

This extends `Recursive.lean`'s existing two-combinator toolkit (`mapPairCode`, itself built
  from
`foldCode`) with a genuine nested fold: an outer fold over `c1` whose accumulator at each
  step
is extended by an inner fold over `c2` (via `appendCode`, list concatenation on codes). Since
  the
downstream use (`combineIntervals`, realizing set unions) never cares about list order or
  duplicates, correctness is stated at the level of list membership, not exact list equality
  --
this sidesteps tracking the reversals `foldCode`'s left-to-right consing introduces.

Everything here is `subsq` {propext, Quot.sound}`.

/--! ### `flatMapCode`: `f x` (list-valued) flat-mapped over a coded list

Like `crossInner`, but the per-element operation `f` returns the *code of a list* to be
**appended** (`appendCode`) onto the accumulator, rather than a single value to be *consed* --
the
code-level analogue of `l.flatMap (fun y => decodeList (f x y))`. This is the piece
`Theorem88b`'s interval-*difference* needs: subtracting a whole interval-list from a single
interval can produce `0`, `1`, or `2` result-pieces per step, so the per-element result is
itself
list-valued. -/

# Primitive-recursive interval-list arithmetic for `?` (Definition 8.7)

Builds the code-level analogue of `Definition87.lean`'s `List (? x ?)` interval-presentation
machinery: encoding `List (? x ?)` by `Nat` (reusing `RationalPrimrec.lean`'s rational codes
and
`Recursive.lean`'s `encodeList`), a genuinely `Nat.Primrec` **`combineCode`** realizing
`combineIntervals` at the code level (via `RecursiveCross.lean`'s `crossCombine`), and a
**canonicalization** `canonCode` that clips every code to a bona fide `?-neighbourhood (
  nonempty,
  `subseq [0,1)`), needed so `?'`'s eventual `ComputablePresentation.X` (`Definition71.lean`)
  is *total*
(every code indexes an actual neighbourhood).

All the `Nat.Primrec`/encoding results here are `subseq {propeq, Quot.sound}`. The set-
level correctness
lemmas (`presentedIntervals_decodeQPairList_combineCode` and its helpers) additionally report
`Classical.choice` in `#print axioms`, but -- exactly as documented in `Definition87.lean`'s
own
"Axiom footprint" section -- this is inherited from the *pinned Mathlib's* `?'` order instance
itself
being `Classical.choice`-tainted, not from any classical reasoning performed in this file.

/-! ## Interval-list *difference*, needed for subset/equality decidability

`ComputablePresentation`'s relations (i)/(ii) (`Definition71.lean`) both ultimately reduce to
deciding whether one presented set is *empty* or a *subset* of another. Non-emptiness is a
cheap
bounded-`exists` (`p.1 < p.2` for some `p` in the list, via `Recursive.lean`'s `existsListChar
`), but
subset needs genuine interval-covering arithmetic: `L1 subseq L2 <-> presentedIntervals
L1 \ presentedIntervals L2
= {}`, computed here by an explicit `diffLists`. As with `combineIntervals`, everything is
built from
the *unconditional* identity `Set.Ico_diff_Ico` (no side conditions on endpoint order), first
at the
pure list level (`diffOneList`/`diffSingleList`/`diffAllList`/`diffLists`), then mirrored at
the

```

```

`Nat.Primrec` code level (`diffOneCode`/`diffSingleCode`/`diffAllCode`/`diffCode`) via
`RecursiveCross.lean`'s `flatMapCode`. -/

/-- **Unconditional interval difference**: `Ico a b \ Ico c d = Ico a (b sqcap c) U Ico (a
sqsup d) b`, with

/#!/ ## Decidability of non-emptiness, subset, and equality of `presentedIntervals`

`ComputablePresentation`'s relations (i)/(ii) (`Definition71.lean`) reduce, via `?`'s canonical
enumeration (Part 3), to deciding membership questions about `presentedIntervals`-coded sets.
The
key primitive is non-emptiness: `presentedIntervals L` is non-empty iff some pair `p` in `L`
  has
`p.1 < p.2` (`presentedIntervals_nonempty_iff`), a cheap bounded-`exists` over the list
(`Recursive.lean`'s `existsListChar`). Subset and equality then reduce to non-emptiness of
`diffCode`, reusing `presentedIntervals_decodeQPairList_diffCode` above -- no new arithmetic is
needed. -/

/-- **A presented union of intervals is non-empty iff some pair in the list is itself non-
degenerate**
(`p.1 < p.2`): every degenerate pair contributes the empty interval, and a single non-
degenerate pair
already witnesses non-emptiness (via its left endpoint). -/
theorem presentedIntervals_nonempty_iff (L : List (? x ?)) :
  (presentedIntervals L).Nonempty <-> exists p in L, p.1 < p.2 := by
  constructor
  * rintro <x, hx>

# Theorem 8.8(b), Part 3 -- `?` (Definition 8.7) has a genuine `ComputablePresentation`

Assembles `Definition71.lean`'s `ComputablePresentation U` from `IntervalPrimrec.lean`'s code-
level
interval arithmetic and decidability results, proving `U.IsEffectivelyGiven`.

## The enumeration

Every natural `c` codes a `List (? x ?)` (`decodeQPairList`), but not every such list
presents a
genuine `U`-neighbourhood (it may be empty, or stray outside `[0,1)`). `canonList` **
canonicalizes**
an arbitrary list to one that does: clip every pair into `[0,1)` (`qpClip`, mirroring
`Definition87.lean`'s private `clip`) and discard now-degenerate pairs, falling back to the
single
pair `(0,1)` (presenting `U.master`) if nothing survives. `canonList_fixed` is the key reuse
lemma:
canonicalizing a list that **already** presents a `U`-neighbourhood changes nothing (as a set)
-- this
drives both `surj` (every `U`-neighbourhood has a Scott-literal presenting list, by `
U_mem_iff_scott`,
on which `canonList` is a no-op) and `inter_spec` (the raw `combineCode` output, when non-empty
, is
already a `U`-neighbourhood, so re-canonicalizing it is also a no-op).

`canonCode` mirrors `canonList` at the `Nat.Primrec` level (`canonListCode` performs the clip/
filter
via `RecursiveCross.lean`'s `flatMapCode`; a final `selectFn`/`isZero` test supplies the `(0,1)
fallback), with `presentedIntervals_decodeQPairList_canonCode` bridging the two. `X n :=
presentedIntervals (decodeQPairList (canonCode n))` is then `?'s enumeration, and Scott's two
relations reduce directly to `IntervalPrimrec.lean`'s `recDecidable_2_presentedIntervals_eq`/
`recDecidable_presentedIntervals_nonempty` (intersection is a *raw* `combineCode`, and -- since
`U`
is so permissive -- is automatically a genuine `U`-neighbourhood whenever it is non-empty, so
"consistent" reduces to "non-empty").

# Theorem 8.8(b), Part 4 -- an explicit, deterministic `splitU`

`Definition87.lean`'s `U_no_minimal` shows every `U`-neighbourhood splits into two proper
disjoint
`U`-neighbourhoods, but only as a bare existential (`exists Y Z, ...`), built via `Classical`-
flavoured
case analysis on an arbitrary witness of non-emptiness. Theorem 8.8(b)'s eventual `Y_n` chain
(Part 6) needs to *compute* such a split from an index `n` alone -- so here we replace the
existential by a genuinely `Nat.Primrec` pair `splitULeft`/`splitURight : Nat -> Nat`, and
reprove
`U_no_minimal`'s four properties (disjoint, covering, both proper) for this canonical choice.

## The construction

Given an index `n`, canonicalize it (`canonCode n`, Part 3) to get a genuine presenting list,
all
of whose pairs are already non-degenerate (`forall_lt_decodeQPairList_canonCode`). Take its
**first** pair `p_0 = decodeRatPair (firstElemCode (canonCode n))` (no search needed -- the *
first*
pair always works, unlike `U_no_minimal`'s arbitrary witness of non-emptiness) and split at its
rational midpoint `m := (p_0.1 + p_0.2)/2` (`ratMidCode`, computed with no genuine division --
see
`RationalPrimrec.lean`): `splitULeft n` re-clips every pair of `canonCode n` into `(- inf , m)`
(`clipLtListCode`), `splitURight n` into `[m, inf)` (`clipGeListCode`). Both are realized at
the code
level via `RecursiveCross.lean`'s `flatMapCode`, threading `m` through as the fixed parameter.

Correctness (`UX_splitULeft`/`UX_splitURight`) shows these compute exactly `X_n I (- inf , m)`
/
`X_n I [m, inf)` as *sets*, mirroring `U_no_minimal`'s own proof almost verbatim; `
splitU_disjoint`/
`splitU_union`/`splitU_left_ne`/`splitU_right_ne` package the four properties.

# Theorem 8.8(b), Part 5 -- decidable `D`-side atom emptiness

`Theorem88.lean`/`Theorem88a.lean` build Scott's back-and-forth construction for the general
(non-effective) Theorem 8.8(a): at each step, `exists_split` classically case-splits on whether
a
`D`-side atom `A` (or `A ∩ X_n`, `A \ X_n`) is empty. For the effective refinement (8.8(b))
we need
this decided, not merely known, from an explicit `ComputablePresentation P` of `D`.

## The `idxSet` reindexing, revisited

Following `Theorem88a.lean`'s key idea, we track atoms not as literal subsets of `a` (arbitrary
Boolean combinations of `D`-neighbourhoods, generally not themselves `D`-neighbourhoods) but
as
subsets of the index set `Nat`, via `idxSet P.X n = {m ? X? subseq X_n}`. A finite sign-
constraint atom
is then
...

```

```

DAtom pos neg := {m ? (forall i in pos, X? subseq X_i) /\ (forall j in neg, not (X
  ? subseq X?))}
...

```

for two lists `pos, neg : List Nat` of `D`-indices (the "+" and "?" targets so far). This is
 exactly `genAtom (idxSet P.X) Set.univ ? n` for the sign sequence `?` matching `pos`/`neg`.

Why this is decidable (and the general `(?)`-style union trick is not needed)

The positive part's (non-)emptiness reduces to *iterated pairwise consistency*: fold `P.inter`
 across `pos`, checking `P`'s own consistency decider (`cons\_computable`) at each step
 (`meetFold`/`meetStep`). This produces a `{ok, idx}` pair: `ok = 1` iff `{X\_i ? i in pos}` is
 jointly
 witnessed-consistent, in which case `idx` indexes the *exact* meet `{?\_{i in pos} X\_i`
 (`meetFold\_spec`, generalizing `idxSet\_inter\_of\_inter\_eq` along the fold).

Given that, the *negative* constraints are handled with no extra machinery at all: `idx` is the
 greatest index satisfying every positive constraint (`X? subseq X\_i` for `i in pos`
 forces
 `X? subseq X\_idx`, by construction of the meet), so

```

* if `X_idx subseq X?` for *some* `j in neg`, **every** candidate `m` inherits `X?
  subseq X_idx subseq X?`, so the
  full atom (positive *and* negative constraints) is empty;
* otherwise `idx` itself already satisfies every negative constraint (`not (X_idx subseq X
  ?)` for all
  `j in neg`, directly checked), so `idx` witnesses the atom is non-empty.

```

So `DAtom pos neg` is empty iff `ok != 1` **or** `X\_idx subseq X?` for some `j in neg`
 -- a bounded check
 against `P`'s own `incl\_computable`, decidable with no union/positivity lemma needed
 (`DAtom\_eq\_empty\_iff`). This is packaged as `Nat.Primrec` (`DAtomEmptyChar`) and, finally, as
 `RecDecidable\_2` (`DAtom\_recDecidable`), extracting `P`'s two deciders inside the (`Prop`-
 valued)
 `RecDecidable\_2` goal -- choice-free, following the `PDPresentation`/
 PowerDomain_isEffectivelyGiven`
 pattern of `Proposition710.lean`.

# Theorem 8.8 (Scott 1981, PRG-19, Lecture VIII) -- `U` is universal

Following Dana Scott, *Lectures on a Mathematical Theory of Computation*, PRG-19, Theorem 8.8:

> The system `U` is universal in the sense that, for every countable neighbourhood system `D`,
  we
> have `D ≤ U`. Moreover, if `D` is effectively given, then the projection pair making the
> embedding can be taken as computable. Indeed there is a correspondence between effectively
> presented domains and the computable, finitary projections of `U`.

This file works towards **Theorem 8.8(a)**, the general (non-effective) half of the theorem:
  every
*countable* `D` embeds as a subsystem of `U`, up to isomorphism.

## Scott's construction

Enumerate `D = {X_n | n in Nat}` (with `X_0 = Delta = D.master`). Scott builds `Y_n` in `U`
  recursively so
that, for every `n` and every `?` in `{+,-}?`, writing `?X := X` if `? = +` and `Delta \ X` if
  `? = -`,
the **atom** `?_{i<n} ?_iX_i` is empty iff the corresponding atom `?_{i<n} ?_iY_i` is empty --
  call this
invariant `(?)`. Once built, matching `X_i` to `Y_i` realizes the embedding.

## This file's encoding

Rather than track the atoms via dependent `Fin n -> Bool` tuples, we track them as a `List (
  Set a x
Set ?)` of matching *pairs* `(A, B)` (the `D`-side atom and its paired `U`-side atom), which

```

```

doubles in length at each step -- this is exactly `(?)` unpacked into `List` bookkeeping (
  matching
this codebase's usual idiom for finite combinatorial data, e.g. `presentedIntervals`'s own `
  List`
representation), avoiding `Fin`-indexed dependent recursion entirely.

**The key local step (`exists_split`)**: given one matching pair `(A, B)` and a new target `X_n`
`,
produce the two refined pairs for `A ∩ X_n` and `A \ X_n`. Remarkably, all three of Scott's
cases are
handled *without* ever needing a general "U-neighbourhoods are closed under set difference"
lemma:

* `A ∩ X_n = {}` : the new pairs are `({}, {})` and `(A, B)` (unchanged) -- no computation
  needed.
* `A \ X_n = {}` (i.e. `A ⊆ X_n`): the new pairs are `(A, B)` (unchanged) and `({},
  {})`.
* otherwise (`A` is genuinely split by `X_n`): both `A ∩ X_n` and `A \ X_n` are non-empty, so
  (by the
  matching invariant on the old pair) `B` is a genuine, non-empty `U`-neighbourhood -- split it
  via
  **Definition 8.7's `U_no_minimal`** into disjoint proper non-empty pieces `Y, Z` with `Y ∪
  Z = B`;
  take `I := Y`, and `B \ I = Z` comes *for free* from `U_no_minimal`'s own conclusion, again
  with
  no separate set-difference-closure lemma required.

**Remaining work** (tracked in `arxiv.md`, not yet in this file): package `exists_split` into
the
`List`-of-pairs recursive construction of the full sequence `Y : Nat → Set`, derive the
inclusion
correspondence `X_i ⊆ X? ↔ Y_i ⊆ Y?` from the atom invariant, and
assemble the final `exists D' : Neighbor
hoodSystem ?, D ≈ ? D' /\ D' ? U` statement. `Classical.choice` is expected and acceptable
throughout
this file's `Theorem 8.8(a)` development: it is a genuinely non-constructive `Prop`-level
existence
statement for an *arbitrary* countable `D` (Scott's own remark that the effective case needs
the
*additional* `? ≈ ??` preparation, absent here, to make the case-splits decidable rather
than merely
classical, is the substance of the follow-up Theorem 8.8(b)).

family `Z : Nat -> Set b` relative to a master set `M` (Scott's `Delta` on the `D`-side, `U.
master` on
the `U`-side). We deliberately index by *all* of `Nat -> Bool` rather than `Fin n -> Bool` :
since
`genAtom Z M ? n` only ever inspects `? 0, ..., ? (n-1)` (`genAtom_congr` below), this
sidesteps
`Fin`-indexed dependent bookkeeping entirely for every *characterization* lemma, at the cost of
harmless redundancy (many `?` present the same atom). A genuine finite index type (`Fin n ->
Bool`)
only reappears once, locally, when a *finite union* is actually needed (`Yseq`, below). -/

/-! ### Packaging `exists_split` as a total choice function

**Generalization for Theorem 8.8(b).** Everything from `atomU` onward in this file is stated
relative to an *abstract* splitting operation `split : Set a -> Set ? -> Set a -> Set ?
x Set ?`
satisfying `SplitSpec` -- exactly `exists_split`'s conclusion, packaged as a total function
rather
than a dependent existential. Theorem 8.8(a) (`Theorem88a.lean`) instantiates this with the
classical `splitChoice` below (via `Classical.choice` on `exists_split`'s existential -- the *
only*
place non-constructivity enters this file). Theorem 8.8(b)'s effective refinement
(`DAtomDecidable.lean` onward) instantiates the *same* generic theorems with a **computable**
`spliteff`, built from `SplitU.lean`'s deterministic `splitU` and `DAtomDecidable.lean`'s
decidable
atom-emptiness test -- getting the entire invariant/transfer apparatus below "for free", with
no
need to reprove any of it. -/

/-- **The abstract specification a splitting operation must satisfy** -- exactly `exists_split`
`s`

```

```

conclusion, as a `Prop` about a *total* function `split`. Both the classical `splitChoice` (via
`Classical.choice`) and the effective, computable `splitEff` (Theorem 8.8(b)) satisfy this. -/
def SplitSpec (split : Set a -> Set ? -> Set a -> Set ? x Set ?) : Prop :=

/-! ### The `U`-side atoms, built via an abstract splitting operation

Fix the enumeration `X : Nat -> Set a` of `D` and its master `Delta := D.master`, and a
splitting
operation `split` satisfying `SplitSpec`. The `D`-side atom at depth `n` for sign sequence `?`
is
simply `genAtom X Delta ? n` (no new definition needed). The `U`-side atom `atomU split X Delta
? n` is
built by recursion, splitting the *previous* atom via `split` against the *next* target `X n`,
taking the `? n`-side of the split. -/

```

```

# Theorem 8.8(a) (Scott 1981, PRG-19, Lecture VIII) -- assembling `D` ~ = ? D' /\ D' ? U`

`Theorem88.lean` builds, for any sequence `X : Nat -> Set a` and master `Delta : Set a`
with
`Delta.Nonempty`, a sequence `Yseq X Delta : Nat -> Set ?` satisfying the finite-constraint
transfer laws.
This file supplies the missing final ingredient and assembles Theorem 8.8(a) in full.

## The `D?` preparation (Scott's "without loss of generality `?` ~ = ??`")

Feeding an arbitrary countable `D`'s own enumeration `e : Nat -> Set a` directly into `Yseq`
is
not enough: `Subsystem.inter_closed` demands that whenever `Y_i I Y?` happens to be a
genuine
`U`-neighbourhood (which, since `U` is so permissive, happens whenever it is merely non-empty
as a
raw set), the pulled-back `X_i I X?` must already be a `D`-neighbourhood. This can fail for a
perfectly good `D` where `X_i, X?` overlap as raw sets without being *witnessed-consistent*
(`Scott 1981`, Definition 7.9's discussion: `X I Y = (X I Y)`, empty exactly when `{X,Y}`
is
not consistent in `D`, regardless of whether `X I Y != {}` as sets). Scott's fix is to
replace `D`
by `D? = {X ? X in D}` (down-sets in `D`'s own neighbourhood order) before running the
construction.

We implement this by reindexing over `Nat` rather than building a `D?` `NeighborhoodSystem`
structure by hand: set

...
X' n := {m : Nat ? e m subseq e n} (Scott's `(e n)`, as a subset of the index set
Nat)
Delta' := Set.univ (Scott's `Delta = D`, i.e. "all indices")
...

and feed `(X', Delta')` into `Yseq`. Three facts drive everything below:

```

```

* `X' n` is **always non-empty** ( $n \in X' n$ ), sidestepping any `Delta.Nonempty`/{}`-
  freeness worries.
* `X' i subseq X' j <-> e i subseq e j` (`idxSet_subset_iff`): the *raw* inclusion
  order on indices matches
  `D`'s inclusion order on neighbourhoods, so `transfer_subset_iff` transfers `D`'s own order
  exactly (`embed_subset_iff`).
*  $e i \cap e j = e m \rightarrow X' i \cap X' j = X' m$  (`idxSet_inter_of_inter_eq`) is a **
  definitional**
  rewriting (no transfer needed): this is what repairs the `inter_closed` gap, because `D`'s
  own
  `inter_mem` axiom (not any separation hypothesis) is what supplies the witness m with
   $e i \cap e j = e m$  whenever  $\{e i, e j\}$  is witnessed-consistent -- and *only* then.

# Theorem 8.8(b), Part 6 -- the effective back-and-forth construction

`Theorem88.lean`/`Theorem88a.lean` build Scott's back-and-forth construction generically over
an
abstract splitting operation `split` satisfying `SplitSpec`; Part 5 (`DAtomDecidable.lean`)
shows
`D`-atom emptiness is recursively decidable for any `ComputablePresentation P` of `D`. This
file
assembles the effective instantiation: a computable splitting operation `splitEff`, built
from
`DAtom_recDecidable` (deciding which side of a `D`-side split is non-empty) and `SplitU.lean`'s
`splitULeft`/`splitURight` (deterministically splitting the matching `U`-side neighbourhood).

## Part 6b: re-pointing `P`'s enumeration at index `0`

`Theorem88a.lean`'s apparatus (`Yidx`, `DprimeU`, `domainIso`) is stated for an arbitrary
enumeration `e : Nat -> Set a` with `e 0 = D.master` (Scott's convention `X_0 = Delta`,
needed for
`Yseq_zero_eq_master`). An arbitrary `ComputablePresentation P` need not have `P.masterIdx =
0`, so
we re-point it: `eIdx` swaps `0` and `P.masterIdx` (a primitive-recursive involution), and
`P.reindexInvolutive eIdx ...` (Definition71.lean) transports the entire computable
presentation
along this swap in one step -- giving a new presentation `P_0` with `P_0.X 0 = D.master` for
free,
with no need to redo any of Part 5's `DAtom` apparatus (it applies to `P_0` exactly as it did
to
`P`).

/-! ## Part 6c: `genAtom (idxSet e)` emptiness is decidable

`Theorem88.lean`'s `genAtom` tracks the depth-`n` atom for a sign sequence `?` as a *set*,
built by
an `if ? i then Z i else M \ Z i` intersection at each step. `DAtomDecidable.lean`'s `DAtom`,
by
contrast, tracks the *same kind* of atom (for `Z := idxSet Q.X`, `M := Set.univ`) as two
explicit
`List Nat` accumulators (`pos`/`neg`) -- the very data a primitive-recursive realization needs
to
carry. `posnegList` extracts these accumulators from `?` by mirroring `genAtom`'s own recursion
step-for-step, so `genAtom_eq_DAtom` (below) is a one-line induction, not a `List.range`/
filter`
reindexing exercise. -/

/-- **The `(pos, neg)` accumulator pair for a sign sequence `?`, at depth `n`.** Mirrors
`genAtom`'s own recursion: at step `n`, `n` itself joins `pos` (if `? n = true`) or `neg`
(otherwise). -/

# Theorem 8.8(b), Part 6d/6e -- `D` (Theorem 8.8(a)'s own subsystem) is effectively given

`Theorem88b.lean` (Part 6a-6c) reduces `genAtom (idxSet e)`-emptiness to `DAtom`-emptiness,
which
Part 5 (`DAtomDecidable.lean`) already decides. The original Part 6d/6e plan tried to go one
step
further: build an explicit, *computable* replacement `splitEff` for `splitChoice` (Theorem 8.8(
a)'s
classical splitting operation), tracking a `U`-code `atomUCode` alongside the abstract `Set`-
level
recursion, so that `Yidx e n` itself could be read off as an explicit `U`-code. That plan hit a
genuine wall (recorded in `HANDOFF.md`'s "design pitfall" entry): `SplitU.lean`'s `splitULeft`/

```

`splitURight` split against the **specific** code fed in (via `canonCode`'s first pair), not against the **set** `B` alone, and two different codes for the same set can canonicalize to different first pairs -- so there is no way to make an abstract, **Set**-valued **splitEff** agree, code-for-code, with an independently-built primitive-recursive tracker without first building a genuine canonical-form (sort+merge) normalization of **List (? x ?)**, a substantial undertaking of its own.

The resolution: never compute **Yidx e n**'s value as a code at all

****The key realization****: **ComputablePresentation**'s **X : Nat -> Set a** field is **data**, not required to be "computable" as a function producing explicit codes (**unitPresentation**'s constant **X _ := Set.univ** is the existing sanity check for this). All that must be **decidable** are the two ****index relations**** (**interEq_computable**, **cons_computable**) and the primitive-recursive **inter** index function. So

instead of computing **Yidx e n**'s value, we show its **index relations** reduce directly to facts already decided by Parts 5-6c, via **Theorem88.lean**'s existing generic transfer lemmas -- with

****no new splitting operation, no canonical forms, and no exponential atom-union machinery**** needed:

** Yidx e i I Yidx e j = Yidx e k transfers (*transfer_inter_eq_iff*) to idxSet e i I idxSet e j = idxSet e k, which unfolds (*idxSet_inter_eq_iff_DAtom*) to (e k subseq e i) /\ (e k subseq e j) /\ (DAtom (P0 P) [i, j] [k] = {})* -- three small, fixed-size decidable facts (two *incl_computable* queries, one *DAtom_recDecidable* query at 2-element/1-element lists).*
** exists k, Yidx e k subseq Yidx e i I Yidx e j transfers (*embed_subset_iff*, twice) to exists k, e k subseq e i /\ e k subseq e j, which is *literally* (P0 P).cons_computable's own predicate -- reused verbatim.*
** The intersection index itself is *literally* (P0 P).inter n m (Scott's own index, reused): its correctness transfers via (*idxSet_inter_of_inter_eq* + *transfer_inter_eq_iff*).*
** The master index is 0 (*Yidx_zero*, already proved in *Theorem88a.lean*).*

This packages into **DprimeUPresentation**, a genuine **ComputablePresentation (DprimeU D (e P) ...)** --

i.e. ****Theorem 8.8(a)'s own *D* (no new construction!) is effectively given whenever **D** is******. This**

completes Part 6 of Theorem 8.8(b): the recursive **Y_n**-chain now has a certified effective witness/verifier (its index relations are decidable), ready for Part 7's **IsComputableMap** work on

the embedding/projection pair **Subsystem.inj*/Subsystem.proj* (*D ? U*, via **DprimeU_subsystem**).*

Everything here is ****choice-free at the *Nat.Primrec* core**** (the deciders extracted from *(P0 P).cons_computable/*incl_computable/*DAtom_recDecidable** are plain primitive-recursive functions); the presentation's **X**-field itself (**Yidx e**) is unavoidably classical (built via **splitChoice**), exactly like **unitPresentation**'s trivial **X** field is "just data".

/-! ## A general `idxSet`/`DAtom` fact: 2-point atom emptiness characterizes `idxSet`-
intersection -/

/-- **`idxSet`-intersection, characterized by a single `DAtom` emptiness query.** For *any*
computable presentation `Q`, `idxSet Q.X i I idxSet Q.X j = idxSet Q.X k` iff `Q.X k` refines
both
`Q.X i` and `Q.X j` (Scott's own decidable inclusion) *and* the depth-2 atom `DAtom Q [i,j] [k]`
(positive constraints `{i,j}`, negative constraint `{k}`) is empty. The three pieces are each
decidable (`incl_computable` used twice, `DAtom_recDecidable` at a fixed 2-element/1-element
list
pair), so this is
the bridge that lets Part 5's `DAtom` apparatus decide `idxSet`-level *equations*, not just
emptiness. -/

# Theorem 8.8(b), Part 7 -- a genuinely computable back-and-forth construction

Part 6 (`Theorem88c.lean`) showed Theorem 8.8(a)'s *classical* subsystem `D' = DprimeU` (built
via
`splitChoice`) is effectively given as an abstract domain in its own right. That is not
enough
for Part 7: `IsComputableMap` needs the *cross*-relation between `D` and `U` -- concretely,
`Yidx e n subseteq UX m` -- to be recursively enumerable, and `Yidx e n`'s actual position
among `U`'s
rational intervals is, by construction, whatever `Classical.choice` happened to pick. There is
no
effective handle on it at all, so no relation mentioning it can be shown r.e.

This file therefore builds a fresh, genuinely computable back-and-forth construction,
replacing Theorem 8.8(a)'s abstract, `Set`-valued splitting recursion (`Theorem88.lean`'s
`atomU`/`split : Set a -> Set ? -> Set a -> Set ? x Set ?`) with one that works 
natively on `U`-codes
throughout, so that at every step there is an actual `Nat`-code in hand -- never a `Set ?`
value
conjured by choice.

## Why the original `atomUCode`/`splitEff` plan failed, and how this one differs

The design pitfall recorded in `HANDOFF.md` (2026-07-02) was: to reuse `Theorem88.lean`'s *
generic*
apparatus, `split` must be a total function of `Set`s** (`Set a -> Set ? -> Set a ->
Set ? x Set ?`).
Given only a *set* `B`, there is no way to effectively recover "the" code for it (`canonCode`
is not
unique-per-set, so `splitULeft`/`splitURight` -- which key off a code's specific first interval
-- can
give different answers for different codes of the same set). Any attempt to define `splitEff`
as a
function of `B : Set ?` alone (e.g. via `Classical.choice`/`Nat.find` to pick a representative
code)
is therefore not provably the same split an independently-built code tracker would compute.

**This file sidesteps the problem instead of solving it**: it never builds a `Set`-valued `
split`
function at all, and does not reuse `Theorem88.lean`'s generic `atomU`/`Yseq`/`transfer_*`
machinery.

```

Instead, the entire back-and-forth recursion is defined **natively** as a ``Nat.Primrec`` function of
 of
``(depth, sign-sequence-code)``, carrying an explicit ``U``-code as part of its state from the very
 first step -- so "which code represents ``B``" is never a question, only ever "the code my own
 recursion already computed". The three ingredients, all already built:

- * Part 4 (``SplitU.lean``): ``splitULeft`/`splitURight``, a deterministic, ``Nat.Primrec`` midpoint split
 of **any** ``U``-code, with ``UX_splitULeft`/`UX_splitURight`` holding **unconditionally** (no side
 conditions on the input code) -- this is what makes composing it across recursion steps
 trivial.
- * Part 5 (``DAtomDecidable.lean``): ``DAtom_recDecidable (P0 P)``, deciding whether a finite
 Boolean
 atom-constraint on ``D``'s neighbourhoods is empty, extracted as a genuine ``Nat.Primrec``
 function.
- * ``DAtom``'s monotonicity under adding constraints (``DAtom (i :: pos) neg subseq DAton pos neg``, via
``IPos_cons``): once a ``(pos, neg)``-atom is detected empty, every further extension of it is
 automatically detected empty too, by the **same** decider, with **no** extra "already empty" flag
 needed in the recursion state.

Status

This file lays the **foundational recursion** (``atomUCode``, ``Nat.Primrec``), its **per-step** ``D``-
 side
 correctness (``genAtom_atomUCode``), and now **Theorem 8.8(b)(vii)(1)**, the full ``atomUCode``
 invariant: ``atomUCode_mem`` (validity, unconditional -- ``UX`` is a total surjection onto ``U``'s
 neighbourhoods, so this needs no emptiness hypothesis at all, unlike ``Theorem88.lean``'s ``atomU``
``)` and
``atomUCode_disjoint`` (atoms for bit-sources disagreeing below depth ``n``, and **both** still ``D``-
 side
 non-empty, are ``U``-side disjoint). The restriction to non-empty atoms is unavoidable and
 harmless:
``atomUCode_eq_zero_of_empty`` shows a once-empty atom's code freezes at the junk value ``0``
 forever, so
 every junk atom aliases to the same ``UX 0`` -- disjointness genuinely fails there, but ``(vii)(2)``
``s``
``YseqCode`` filters junk ``k``'s out of its union, so this restricted invariant is exactly what is
 needed downstream.

The remaining assembly (Part 7b: a ``Yseq``-analogue as a **union** over ``2``? such atoms,
 disjointness,
 subset/intersection transfer, ``D``'s ``NeighborhoodSystem`/`ComputablePresentation``,
``D ~ ? D``'s ``U``; Part 7c: ``IsComputableMap`` itself) is **not yet done** -- see ``HANDOFF``
`.md`` for
 the detailed continuation plan. Nothing in this file is a placeholder or ``sorry``; everything
 proved
 here is a real, checked, reusable building block for that continuation.

/-! ## The code-native atom recursion

Fix `P : ComputablePresentation D` and work relative to `P0 P` (Part 6b's re-pointed
presentation,
`(P0 P).X 0 = D.master`). The recursion state at depth `n`, for a fixed bit-source `k` (`k`'s
bit
`y` records the sign `? y` in {true, false}` of the depth-`y` step), is packed as

`pair remK (pair posC (pair negC uCode))`

```

where ``remK`` is the **unconsumed** suffix of ``k`` (peeled one bit at a time via ``/2``, avoiding the need for a general ``Nat.Primrec`` division-by-``2^y``), ``posC``/``negC`` are ``encodeList``-style codes for the accumulated positive/negative index lists (Part 6c's ``posnegList``, built by ***prepending*** instead of appending -- harmless, since ``DAtom``/``IPos`` only ever care about list **membership**), and ``uCode`` is the ``U``-code of the matching ``U``-side atom (meaningful only when the ``D``-side atom is non-empty). -/

/-! ## Theorem 8.8(b)(vii)(1) -- the `atomUCode` invariant

Unlike `Theorem88.lean`'s `atomU` (valued in genuine `Set ?`, where `{}` is an honest value),
`UX : Nat -> Set ?` is a total surjection onto `U`'s neighbourhoods* (`U_mem_UX`,
    unconditional:
`canonCode`'s degenerate-input fallback is `U.master`, never `{}`) -- no code represents the
    empty
set. So the right invariant here is not `atomU_invariant`'s emptiness-matching clause "(?)"
verbatim; instead:

* validity holds completely for free, for every code (`U_mem_UX`), empty match or not;
* disjointness only holds, and only needs to hold, between two atoms that are both still
  `D`-side non-empty (`atomUEmpty = 0`) -- once a bit-source's atom goes empty its code is
    frozen at
    the junk value `0` forever (`atomUCode_eq_zero_of_empty` below), and all junk atoms alias
    to the
    same `UX 0`, so disjointness genuinely fails between two junk atoms (or junk vs. non-junk)
    and must
    be excluded; `(vii)(2)`'s `YseqCode` filters junk `k`'s out of its union, so this restricted
    disjointness is exactly what is needed downstream. -/

/-- D-side atom emptiness at depth `n`, for bit-source `k` -- `1` iff the accumulated
  `(pos, neg)` constraint pair already denotes the empty `D`-index atom. -/

/#!/ ## Theorem 8.8(b)(vii)(2) -- `YseqCode`, Scott's `Y_n` coded

Scott's `Y_n` (`Theorem88.lean`'s `Yseq`) is the union, over the `2?` depth-`(n+1)` atoms with
bit
`n` forced `1`, of the "+"-piece chosen at that step. Here that union is built **as a `Nat.
Primrec`
fold over `U`-codes** (`yFold`/`YseqCode`), skipping any bit-source whose `D`-side atom is
already
junk (`atomUEmpty = 1`) -- since a junk atom's code is *frozen at the aliasing value `0`*
(`atomUCode_eq_zero_of_empty`), and `UX 0 = U.master` (`canonCode`'s degenerate-input fallback)
, a
naive unfiltered union would corrupt every depth's result to `U.master` outright. -/

/#!/ ### Bit-level arithmetic for `deltaOf`, via `Nat.testBit`

`deltaOf` is definitionally `Nat.testBit` in disguise (`Nat.testBit_eq_decide_div_mod_eq`), so
every
fact below is a direct transcription of a core `Nat.testBit` lemma about `2?`-shifted/masked
naturals -- no bespoke bit-manipulation induction is needed. -/

theorem deltaOf_eq_testBit (k i : Nat) : deltaOf k i = k.testBit i :=

/-! ### The union fold: `yFoldStep`/`yFold`

`yFoldStep` is written as a function of a single packed argument `w = pair n (pair i acc)`
(mirroring `atomStep`'s own convention), so that feeding it directly into `Nat.Primrec.prec`
needs
no further unpair/pair bookkeeping. -/

/-- One step of the depth-`n` union fold over bit-sources `i + 2` (bit `n` forced `1`):
silently
skip over `D`-side-empty ("junk") atoms -- whose code is frozen at the aliasing value `0`
(`atomUCode_eq_zero_of_empty`) and would otherwise contribute the spurious `UX 0 = U.master` to
the
union -- and union in every genuine (non-junk) atom's code via `unionUX`. The accumulator is
packed
as `(found, code)`: `found = 0` means "no genuine atom seen among the earlier `i` < `i` yet" (`
code`

```

Lean 4 source (lines 801–1200)

```

is junk and unused in that case); `found = 1` means `code` already holds the union of all
genuine
atoms seen so far. -/
